Abstract

Efficient delivery of growth factors is one of the great challenges of tissue engineering. Polyelectrolyte multilayer films (PEM) made of biopolymers have recently emerged as an interesting carrier for delivering recombinant human bone morphogenetic protein 2 (rhBMP-2 noted here BMP-2) to cells in a matrix-bound manner. We recently showed that PEM made of poly(L-lysine) and hyaluronan (PLL/HA) can retain high and tunable quantities of BMP-2 and can deliver it to cells to induce their differentiation in osteoblasts. Here, we investigate quantitatively by Fourier Transform Infrared spectroscopy (FTIR) the secondary structure of BMP-2 in solution as well as trapped in a biopolymeric thin film. We reveal that the major structural elements of BMP-2 in solution are intramolecular $\beta$-sheets and unordered structures as well as $\alpha$-helices. Furthermore, we studied the secondary structure of rhBMP-2 trapped in hydrated films and in dry films since drying is an important step for future applications of these bioactive films onto orthopedic biomaterials. We demonstrate that the structural elements were preserved when BMP-2 was trapped in the biopolymeric film in hydrated conditions and, to a lesser extent, in dry state. Importantly, its bioactivity was maintained after drying of the film. Our results appear highly promising for future applications of these films as coatings of biomedical materials, to deliver bioactive proteins while preserving their bioactivity upon storage in dry state.

Introduction

Efficient delivery of growth factors is one of the great challenges of tissue engineering. It is now acknowledged that large doses of potent growth factors, delivered in solution, can lead to severe side effects. Engineered materials that can regulate the biological presentation of growth factors represent a new class of therapeutic agents for the treatment of a wide variety of diseases. The ideal carrier would retain and sequester the growth factor locally, thus reducing the dose needed, while enhancing its efficacy. Importantly, the carrier should preserve the protein bioactivity, which is directly related to its secondary and tertiary structure.

The bone morphogenetic protein (BMP) family is an intensive field of research in its own for tissue engineering applications as well as for fundamental cell biology studies due to its physiological importance. BMPs play a crucial role in morphogenesis, tissue patterning and regeneration after tissue damage. In particular, BMP-2 is a highly potent morphogen that induces muscle precursors and mesenchymal stem cell differentiation in bone cells. Currently, BMP-2 is used in clinics and the only approved formulation of BMP-2 uses an absorbable collagen sponge as a carrier agent. However, up to 12 mg (much higher dose than physiological concentrations) is used, thus raising serious concerns about its safety as reported in the recent literature. Other carrier biomaterials have been and are currently being developed. Mimics of the natural extra cellular matrix, including fibrin films, hyaluronan hydrogels, polypeptide and polysaccharides-based layer-by-layer films appear particularly interesting due to their natural composition. Natural biopolymers may not only permit the protein to be presented in a “matrix-bound” manner, but they also provide a water-rich environment. This may be a crucial point for preserving the stability of the proteins in dry state once loaded in the biopolymeric coatings. In fact, dehydration is known to possibly greatly impact proteins structures. The drying process removes part of the hydration layer, which may disrupt the native state of a protein and cause protein aggregation. It is known that protein conformation is very often lost upon storage in dry conditions, unless stabilizers like sugars, polyols or polyaminoacids are added during the freeze-drying process. Very recently, atomistic molecular dynamics simulations suggested that the environment (vacuum versus water) is a key factor in the stabilization of the secondary and tertiary structure of BMP-2. Friess and coworkers have shown that controlled precipitation of BMP-2 proteins from very high solutions of very high concentrations (20 mg/mL) of protein lead to the formation of microparticles of μm size (7 and 35 μm bimodal distribution). They used FTIR spectroscopy to show that the structure of BMP-2 in the precipitated state and after resolubilization in an acidic buffer was similar to that of the protein in solution. They evidenced the formation of mainly β-sheet structures and α-helices. The formation of β-sheets was also observed by circular dichroism.

However, quantitative information on BMP-2 secondary structure in solution or in a carrier material is still lacking. Here, we investigated quantitatively by FTIR the secondary structure of BMP-2 in solution as well as trapped in a nanostructured biopolymeric thin film. The film is a polyelectrolyte multilayer film made of poly(L-lysine) and hyaluronan (PLL/HA), which was recently shown to retain high and tunable quantities of rhBMP-2 and to
deliver it to cells in a “matrix-bound” manner. FTIR was chosen as it is a powerful technique to qualitatively and quantitatively assess protein secondary structure and to obtain the relative amount of different types of secondary structures based on the band areas. It is a very precise (< 2 cm⁻¹), sensitive and reproducible technique, which is indeed routinely used to assess the secondary structure of therapeutic proteins.

**Materials and Methods**

**Materials**

Poly(L-lysine) (PLL) hydrobromide (P2626, 6.8 × 10⁴ g/mol) was purchased from Sigma (St-Quentin Fallavier, France) and hyaluronan (HA, 3.6 × 10⁵ g/mol) was obtained from Lifecore Biomedical (USA). They were dissolved at 0.5 mg/mL and 1 mg/mL, respectively, in a buffered saline (0.15 M NaCl, 20 mM HEPES, pH 7.4, called hereafter HEPES-NaCl buffer). For film cross-linking, 1-Ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC, Sigma, St Quentin Fallavier, France) was mixed with a N-hydroxysulfosuccinimide (sulfo-NHS, Chemrio, China) in 0.15 M NaCl solution (pH 5.5) at concentrations of 30 mg/mL and 11 mg/mL, respectively. BMP-2 was from Medtronic Biopharma BV.

**Quantitative analysis by FTIR spectroscopy**

A Vertex 70 spectrophotometer (Bruker Optics GmbH, Ettlingen, Germany) was used for the acquisition of FTIR spectra. Single-channel spectra were recorded between 400 and 4000 cm⁻¹ with a 2 cm⁻¹ resolution by means of the OPUS Software v6.5 (Bruker). A nitrogen-cooled Mercury-cadmium-telluride (MCT) detector was used to improve the detection level. Such detector is known to produce a noise level 10 to 50 times lower than other detectors.

Different accessories were used depending on the experiments: an Aquaspec transmission cell for studying BMP-2 in solution, an attenuated total reflection (ATR) liquid cell for the study of BMP-2 loaded in hydrated films, and a standard transmission accessory for the study of the BMP-2 loaded films deposited on silicon substrates and subsequently dried. All these accessories were purchased from Bruker Optics. The OPUS Software v6.5 (Bruker GmbH) was used for the treatment and deconvolution of the spectra. Residual water and CO₂ contributions were removed and baseline correction was done manually, choosing always the same reference points in each group of spectra. When residual noise due to water (especially in dry conditions) was still present, the spectra were smoothened using a specific algorithm from Opus software. The frequencies of the different components forming the amide I band were first determined by calculating of the second derivative of the Fourier smoothed spectrum. There was thus no arbitrary decomposition into a preset number of bands and on the peak position. Once the number of component bands was determined, the amide I band was fitted by using the component frequency, width, and intensity as fitting parameters. The more consistent results were obtained when all component peaks were assumed to be Gaussian. The correspondence of each component band with a given secondary structure was established by comparing the frequency of its maximum to the value given in the literature. We defined the relative contribution of each component (in %) by the ratio of the area of each peak over the area of the total amide I band.
Characterization of BMP-2 secondary structure in solution

The BMP-2 solution was first purified. To this end, it was first precipitated using a 10% Ammonium Sulfate (AS) solution. The mixture was centrifuged at 13000 rpm for 10 min after which the supernatant was removed. This procedure was repeated three times with a 2% AS solution. Finally, the protein was resuspended in the 1 mM HCl in D$_2$O (pH=3) solution or in the HEPES-NaCl buffer in D$_2$O (pH=7.4). The final protein concentration was ~2 mg/mL for rhBMP-2 in 1mM HCl (pH 3). At pH 7.4, the protein is known to be less soluble. We estimated the BMP-2 concentration of the resuspended solution to be 400 μg/mL at this pH, based on the difference of the maximum absorbance of the protein. 60 μL of BMP-2 was injected in the Aquaspec cell and a single-channel spectrum of 64 interferograms was recorded.

(PLL/HA) film characterization by FTIR

The buildup of (PLL/HA) films in HEPES-NaCl buffer was followed by FTIR spectroscopy as previously described. For studies in hydrated conditions, D$_2$O was used as solvent instead of water in order to avoid the overlapping water band in the amide I region (O-H bending vibration at 1643 cm$^{-1}$ versus O-D bending vibration at 1209 cm$^{-1}$). The spectra of hydrated (PLL/HA)$_{12}$ films were acquired in situ using attenuated total reflection (ATR) mode. To this end, films were built and cross-linked on a ZnSe crystal and a single-channel spectrum of 64 interferograms was recorded. For studies in dry conditions, films were built as described previously on a ~1 cm$^2$ silicon substrate (Siltronix, France) using HEPES-NaCl (dissolved in H$_2$O) followed by cross-linking. The films were then rinsed with milli-Q water to remove the salt and dried for 1 h at 37°C. The film spectra in transmission were acquired by summing 256 interferograms. For long-term stability measurements, the films were stored in dry state at 4°C. Before each FTIR acquisition, they were incubated for 1 h at 37°C.

Characterization of BMP-2 secondary structure in hydrated and in dry (PLL/HA) films

For BMP-2 trapped in hydrated (PLL/HA)$_{12}$ films built in D$_2$O, BMP-2 was loaded from a solution at 100 μg/mL in 1 mM HCl in D$_2$O (pH=3) following the protocol established previously. The rinsing steps were done with HEPES-NaCl buffer. The spectrum of BMP-2 was obtained by subtracting the spectrum of the film in contact with the HEPES-NaCl buffer to that of the BMP-2 loaded film (measured in the same buffer after rinsing of the film).

For study of BMP-2 in dry films, BMP-2 in 1 mM HCl (in H$_2$O) was loaded in the (PLL/HA) film prepared in the Heps-NaCl buffer (in H$_2$O) and dried as described above for the film. The spectrum of BMP-2 inside dry films was obtained by calculating the difference between the average spectrum of two independent BMP-2 loaded films and the average spectrum of two control samples (i.e. films that have followed the same procedure, except that BMP-2 was not present in the loading solution).
C2C12 cell culture and Alkaline Phosphatase Activity test (ALP test)

Murine C2C12 skeletal myoblasts (< 25 passages, obtained from the American Type Culture Collection, ATCC) were cultured in tissue culture Petri dishes, in a 1:1 Dulbecco’s Modified Eagle Medium (DMEM)/Ham’s F12 medium (Gibco, Invitrogen, France) supplemented with 10% fetal bovine serum (FBS, PAA Laboratories, France), 100 U/mL penicillin G and 100 μg/mL streptomycin (Gibco, Invitrogen, France) in a 37°C, 5% CO₂ incubator. Cells were subcultured prior to reaching 60-70% confluence (approximately every 2 days).

The bioactivity of BMP-2 on C2C12 cells was determined by assaying the alkaline phosphatase (ALP) activity, a marker of osteogenic differentiation, as previously described 15. C2C12 cells were seeded in 24-well plates (90 000 cell per well) in 1 mL of growth medium. After 3 days of culture, the culture medium was removed and the cells were washed with PBS and lysed by sonication (5 s) in 500 μL of 0.1% Triton-X100 in PBS. 180 μL of a buffer containing 0.1 M 2-amino-2-methyl-1-propanol (Sigma, France), 1 mM MgCl₂, and 9 mM p-nitrophenyl phosphate (Euromedex, France) adjusted to pH 10 was added to 20 μL of lysate. The enzymatic reaction was monitored in a 96-well plate by measuring the absorbance at 405 nm using a TECAN Infinite 1000 microplate reader (Tecan, Austria) over 10 min. The total protein content of each sample was determined using a bicinchoninic acid based protein assay kit (Interchim, France). The ALP activity was expressed as mmoles of p-nitrophenol produced per min per mg of protein (pnp/min/mg).

The bioactivity of loaded BMP-2 was also assessed after drying the film and upon storage at 4°C. To this end, the samples were loaded with BMP-2 as previously described and thoroughly washed in HEPES-NaCl buffer then in ultrapure water. They were air-dried for 2 h under a laminar flow hood and stored at 4°C. The BMP-2 activity was determined right after this drying step and after 1 month of storage. The samples were rehydrated 30 min in the HEPES-NaCl buffer and sterilized under UV irradiation before depositing cells. The ALP activity test was performed after 3 days of culture.

Results and Discussion

Secondary structure of BMP-2 in solution at acidic and at neutral pH

The secondary structure of BMP-2 protein was first investigated by FTIR in solution (Figure 1) with a focus on the Amide I band. pH 3 was selected as it corresponds to its maximum solubility 36 and to the recommended conditions of storage. Indeed, we have previously shown that loading of BMP-2 in the biopolymeric film at pH 3 was optimum in terms of homogeneity and loaded amount 15. Physiological conditions (0.15 M NaCl, pH 7.4, Figure 1B), which corresponds to the conditions of film buildup and cell culture experiments, were also studied. Second derivatives of the spectra were also calculated (Figure 1A’, B’). Based on these second derivatives, on FTIR data on proteins 30 and on a previous study on precipitated BMP-2 microparticles 19, the five observed minima were attributed to four different types of secondary structures as follows: ~1630 cm⁻¹ and ~1680 cm⁻¹ to antiparallel β-sheets (two contributions at low and high wavenumbers, LW and HW, respectively), 1645 cm⁻¹ to unordered, ~1651-1657 cm⁻¹ to α-helix, and ~1670 cm⁻¹ to β-turn structures 30.
At first sight, the spectra of BMP-2 at different pHs appeared to differ as its maximum was positioned at 1645 cm$^{-1}$ for BMP-2 at pH 3, whereas it was at 1633 cm$^{-1}$ for BMP-2 at pH 7.4 in the presence of salt. Decomposition of the amide I band allowed the quantification of the respective contributions of each type of secondary structure (Table 1).

Independent experiments indicated that the precision of the peak position obtained by fitting the spectra is $< 2$ cm$^{-1}$. The precision on the % of secondary structures can be estimated at $\sim 3$ to 4% for the most prominent peaks and highest peaks and $\sim 1$-2 % for the smallest ones.

First, one noticed that the highest contribution was that of antiparallel $\beta$-sheets (sum of LW and HW $\beta$-sheet), which accounted for 42% of the structure at pH 3 and 51% at pH 7.4 in the presence of salt. The $\alpha$-helix contribution represented 24% of the secondary structure at pH 3 and only 16% at pH 7.4. Of note, the % of unordered structures remained unchanged ($\sim 24$-27%) in both conditions and the % of $\beta$-turn was also similar ($\sim 7$-9%). Thus, formation of $\beta$-sheet structures was induced by the increase of pH closer to its isoelectric point (8.5 $^{37}$), where BMP-2 is less soluble $^{32}$.

These experimental determinations of the % of secondary structures were indeed relatively close to the values deduced from the crystal structure of BMP-2 $^{38}$ and from molecular dynamics simulations of BMP-2 structure in water $^{17}$. These latter values range from 41 to 52 % for $\beta$-sheets and from 8 to 12% for $\alpha$-helix structures. Experimental data obtained by circular dichroism also indicated the prominence of $\beta$-sheets $^{20}$. In addition, FTIR data on native BMP-2 at very high concentration (20 mg/mL) and on dried microparticles of BMP-2 showed that $\beta$-sheets represented $\sim 25$% of the secondary structural elements $^{18}$. Thus, although performed in different experimental conditions, our data are consistent with these previous experimental and theoretical studies.

**Secondary structure of (PLL/HA) films**

Next, we investigated the structure of the polyelectrolyte multilayer film that was used as reservoir for BMP-2 storage in hydrated and in dry state. This analysis was important to get information on the possible changes in the film structure. We studied the amide I region in different solvents (D$_2$O versus H$_2$O) and in hydrated or dry conditions.

Figure 2 shows the typical infrared spectra of cross-linked (PLL/HA)$_{12}$ films in hydrated and dry states with a focus on the amide I and amide II bands. The spectrum of the hydrated film is shown for films built in D$_2$O and in H$_2$O. The spectrum of dry film was obtained after drying a film prepared in HEPES-NaCl buffer in H$_2$O.

The comparison between the spectra for hydrated films obtained in D$_2$O and in H$_2$O allowed to reveal some differences. The most significant change was the shift of the entire amide II band from 1557 cm$^{-1}$ (maximum of this band) to 1465 cm$^{-1}$ when the film was built in a D$_2$O. This shift can be justified by the hydrogen/deuterium exchange as reported previously in the literature $^{39}$. In (PLL/HA) films, the amide I band is mainly representative of PLL structure $^{40}$. The second derivatives allows to determine the position of the major peak of the Amide I band (Figure 2A$^\prime$). A strong minimum was visible at 1638 cm$^{-1}$ for the film built in D$_2$O, at 1644 cm$^{-1}$ for that built in H$_2$O, and at 1656 cm$^{-1}$ for the dry film, which could be
attributed to unordered structures \(^{40,41}\). Thus there was a significant shift toward higher wavenumbers especially for the dry film (+12 cm\(^{-1}\) after drying the film built in water). This total shift is due to combined effect of solvent exchange and subsequent drying\(^{39}\), as the film was built in D\(_2\)O for studies in hydrated conditions versus H\(_2\)O for studies on dry and stored films. A weaker contribution, attributed to turn structures, was observed at 1663 and 1674 cm\(^{-1}\) for hydrated films and at 1680 cm\(^{-1}\) for dry films. The COO\(^{-}\) contribution was also shifted from ~1600 cm\(^{-1}\) in H\(_2\)O to 1607 cm\(^{-1}\) in D\(_2\)O and ~1612 cm\(^{-1}\) for dry films. A small contribution of COOH of HA was also visible at ~1735 cm\(^{-1}\).

After peak decomposition (supporting information Figure SI1), we found that ~90-95% of the structural elements in (PLL/HA) hydrated or dry films were unordered structures and that only 5-10% were turn structures. We thus conclude that the hydrated (PLL/HA) film exhibited mostly an unordered structure, which was kept after drying the film.

**Structure of BMP-2 trapped in hydrated or dry (PLL/HA) films**

The structure of BMP-2 trapped in hydrated or dry (PLL/HA) films was subsequently investigated (Figure 3). In this case, some interactions between the protein and the film might occur, as BMP-2 has a very strong affinity with the film and remained trapped in it even after extensive washing \(^{15}\). In a previous study, we have quantified the amount of adsorbed BMP-2 that is trapped after thorough rinsing of the film \(^{15}\) as a function of the concentration of the BMP-2 solution used for the loading and as a function of film thickness. For an initial BMP-2 concentration in solution of 100 μg/mL (used here or its loading in the film), this amount was estimated to be of 769 ± 69 ng/cm\(^2\) \(^{15}\). For BMP-2 in hydrated films, we noted at first sight that the absorbance was maximal at ~1644 cm\(^{-1}\), showing similarities with that of BMP-2 in solution at pH 3 (Fig.1A). However, besides the five contributions already observed for BMP-2 in solution, two new but very small contributions appeared at low (~1615, 1628 cm\(^{-1}\)) and high wavenumbers (~1691 cm\(^{-1}\)) for BMP-2 in films, as compared to BMP-2 in solution (Fig. 1). They can unambiguously be attributed to intermolecular β-sheet structures \(^{30}\), which may result from either protein-protein interactions or from protein-polyelectrolyte interactions. All the other peak positions present in the second derivatives were close to those previously observed for the protein in solution. We also performed control experiments to ensure that the contribution of the film to the BMP-2 spectrum was negligible. To this end, the film was subjected to the same sequence of dipping as for BMP-2, except that BMP-2 was not added (Figure SI2). A very small decrease in the 1600-1700 cm\(^{-1}\) region of 0.001 absorbance units, which is 25 times smaller than the BMP-2 signal measured in the amide I band region (Figure 3A). Indeed, a positive absorbance was measured for BMP-2 in the amide I band region.

The deconvolution of the spectrum (Table 1) lead to the most consistent results by now considering seven peaks. BMP-2 in hydrated films mostly formed intramolecular β-sheets (36 %), unordered structures (31 %), α-helix (18 %), β-turn (11 %) and only a very minor fraction of intermolecular β-sheets (3 %). Indeed, the percentages of the different types of secondary structures differed by only few % from those of BMP-2 in solution at pH 3. Thus, although BMP-2 was physically confined in the film, its structure remained close to the one it had in solution at pH 3.

*Biomacromolecules. Author manuscript; available in PMC 2014 July 25.*
At first glance, the spectrum of BMP-2 trapped in a dry film (Fig. 3B) was different when compared to all other conditions (BMP-2 in hydrated film or in solution at different pHs). The maximum of the spectrum was shifted to a higher wavenumber at 1652 cm\(^{-1}\). This shift of ~ 8 cm\(^{-1}\) is reminiscent of the shift observed for (PLL/HA) films built in the Hepes-Nacl buffer (in H\(_2\)O) and dried (Figure 2). It may thus be due to the different experimental conditions used notably i) BMP-2 loading in water and not in D\(_2\)O, which was used for the \textit{in situ} experiments in hydrated films and ii) drying of the BMP-2 loaded film, which restricts the mobility of the polymeric and polypeptidic chains. Furthermore, the two minima previously observed at 1670 and 1680 cm\(^{-1}\), were replaced by a single but more pronounced minimum at 1677 cm\(^{-1}\), which renders the distinction between \(\beta\)-turn and intramolecular \(\beta\)-sheets more difficult. By considering the systematic shift in the peak positions and by still considering 7 contributions, which gave the best fits, we found that BMP-2 in dry films formed unordered structures (34 \%), intramolecular \(\beta\)-sheets (26 \%), \(\alpha\)-helix (21 \%), \(\beta\)-turn (16 \%) and intermolecular \(\beta\)-sheets (3 \%). The most important differences with BMP-2 in hydrated films arose from the decrease in intramolecular \(\beta\)-sheets and the concomitant increase in unordered and \(\beta\)-turn structures.

Thus, FTIR revealed the predominance of \(\beta\)-sheets and unordered structures on BMP-2 trapped in hydrated films and in dry films as well. The fraction of intramolecular \(\beta\)-sheets decreased from 42-51\% for BMP-2 in solution to 25-36 \% for BMP-2 in films, the strongest decrease being observed for BMP-2 in dry films. The \% of unordered structures in trapped BMP-2 was higher (31-34\%) for BMP-2 in films as compared to its solution counterpart (24-27\%). The presence of \(\alpha\)-helix was also confirmed, with an overall percentage of 16-24\%.

**Bioactivity of “matrix-bound” BMP-2 in dry films**

An important question is whether the bioactivity of “matrix-bound” BMP-2 was maintained in dry films, as we already know from our previous studies that BMP-2 loaded in hydrated films is bioactive \(^{15}\). In order to assess the bioactivity of BMP-2, we chose C2C12 myoblast cells as working model. These cells constitute an acknowledged \textit{in vitro} model system to study the ability of BMPs to alter cell lineage from the myogenic to the osteogenic phenotype \(^{42}\); as BMP-2 induced the expression of alkaline phosphatase (ALP). In a previous study, we have already demonstrated that BMP-2 presented in a “matrix-bound” manner from hydrated (PLL/HA) films induced osteoblastic differentiation of C2C12 myoblasts \(^{15}\). Here, the bioactivity of the films was tested either right after their preparation, i.e. in hydrated state, or after drying of the film for a short period (2 h) or after storage of the film in dry conditions for one month. First, we verified by FTIR that the films could be stored in dry state for this time period (Supporting information Figure S13). Only very minor changes of less than 6\% were noticed in the FTIR spectra, especially in the COO\(^-\) peak region and in the amide I band. The ALP test was performed on C2C12 myoblasts after 3 days of contact with the BMP-2 loaded films (Figure 4). A control value for the bioactivity of BMP-2 in solution (i.e. added to the cell culture medium for 3 days) was also obtained in conditions where the bioactivity has reached a plateau value \(^{15}\) (ie for a BMP-2 concentration of 200 ng/mL).
Very interestingly, the BMP-2 loaded (PLL/HA) films dried for 2 h, or dried and stored for 1 month retained a full activity, similar to that of hydrated films and to the plateau value obtained for BMP-2 in solution. It is difficult to precisely quantify the fraction of BMP-2 that is bioactive in the hydrated film, which remained bioactive after drying of the film. But a rough estimate can be made, considering the fact that the ALP response is proportional to the amount of BMP-2 loaded in the films and that a plateau value in the ALP signal was observed for a BMP-2 concentration in film of ~400 ng/cm². As the effective BMP-2 loaded concentration in the film was previously determined to be of ~770 ng/cm² in our experimental conditions, one can infer that at least 52% of BMP-2 was bioactive. Thus, although there was a slight increase in unordered structures upon drying of the BMP-2 loaded film, the overall activity of the protein was still very high after rehydration of the film. The presence of a large number of H-bond in the (PLL/HA) films and large number of water molecules around hyaluronan, even in the dry state, are probably playing an important role in this process. Importantly, the protein is trapped in the film but the structure of the film allowed it to retain a large fraction of intramolecular β-sheets and to maintain its central α-helix. By analogy to sugars that are widely used as stabilizing agents during drying of proteins, the biopolymeric film plays the role of stabilizer, or protective carrier, for the protein.

In conclusion, BMP-2 trapped in hydrated and dry (PLL/HA) films retained its overall secondary structure, but an increase in unordered structures and a decrease of β sheets was noted as compared to BMP-2 in solution.

Importantly, the bioactivity of the dry BMP-2 loaded films remained at a similar level to that of hydrated films, which confirmed the protective role of the film in the stabilization of the BMP-2 structural elements. These results appear highly promising for future applications of these films as coatings of biomedical materials, to sequester proteins and to deliver them locally, while preserving their bioactivity and secondary structure. It would be interesting to investigate whether similar mechanisms may take place for other types of growth factors that have been successfully adsorbed on PEMs films and whose bioactivity was proved.

FTIR spectra and second derivative of BMP-2 trapped in cross-linked (PLL/HA)$_{12}$ films (A, A’) in a HEPES-NaCl buffer at pH 7.4 (hydrated film) and (B, B’) after drying the film (in black: experimental spectrum and in grey fitted spectrum).
Figure 4.
Quantification of alkaline phosphatase activity of C2C12 cells cultured for 3 days in the presence of BMP-2 in solution at 200 ng/mL (control value for BMP-2 bioactivity) or on the (PLL/HA) films loaded or not with BMP-2. Films were either hydrated or dried for 2 hrs, or dried and subsequently stored for a month. There was no statistical difference between the conditions, except for the condition without BMP-2 in the film. Error bars are SEM.
Table 1

Results of the deconvolution of the FTIR spectra of rhBMP-2 in solution at pH 3 (no salt) or at pH 7.4 (HEPES-NaCl buffer) as well as in hydrated or dry polyelectrolyte multilayer films. (LW, HW: Low, High Wavenumber). W: Wavenumber (cm\(^{-1}\)); %: percentage relative to the total amide I band integral.
