Abstract

A hydrochlorination reaction of styrenes catalyzed by Pd^{II} in combination with Cu^{II} was developed, which was followed by an in situ conversion of electron-rich products to an ether in the presence of an alcohol. Mechanistic experiments indicate that olefin functionalization is coupled to an alcohol oxidation, wherein a Pd hydride formed in the β -hydride elimination step of the alcohol oxidation was incorporated into the product.

Introduction

Carbon–oxygen and carbon–halogen bonds are prevalent in organic compounds, and thus, a number of methods exist to achieve their formation.¹ One of the classic ways to form C–O and C–X bonds is the addition of HX or HOR to double bonds, which is typically an acid-catalyzed reaction.¹ Unfortunately, strong acids are often required and do not always lead to high product yields.² To overcome these disadvantages, hydrohalogenation reactions have been developed, where a small amount of acid is formed in situ, thus lowering the concentration of strong acid and providing milder reaction conditions.³ However, to the best of our knowledge, acid catalysis remains the only route used for the addition of HX across alkenes (Figure 1A).

A seemingly different approach has been taken with hydroalkoxylation reactions using metal catalysis. Most of these reactions have been proposed to occur via oxymetallation of the substrate followed by protonation of the resulting metal–carbon bond to regenerate the catalyst (Figure 1B).^{4,5} These transformations are especially well-known for alkenes adjacent to an electron withdrawing group,^{4i, j} but some have also been developed for nonactivated alkenes. Interestingly, most metal catalysts capable of reacting with nonactivated alkenes require triflate counterions,^{4a–g} and Hartwig and co-workers have recently shown that, in at least some of these systems, TfOH is formed in situ, which then acts as the active catalyst.^{6a} Thus, the character of the active catalyst in a number of hydroalkoxylation reactions is questionable, and these reactions possibly proceed via an acid-catalyzed mechanism analogous to that of hydrohalogenation.⁵

Because of the use of rather strong acids in most hydrohalogenation and hydroalkoxylation reactions, poor functional group tolerance is often displayed,⁷ and it thus seems desirable to develop metal-catalyzed variants, which could possibly overcome this disadvantage. In our

laboratory, a hydroalkoxylation of vinylphenols has recently been discovered (eq 1), which is believed to proceed through a mechanism distinct from previously reported hydroalkoxylation reactions.⁸ This reaction was originally thought to proceed via the oxymetallation/protonation mechanism (Figure 1). To test this, the reaction was performed in CH₃CH₂OD, which should result in the incorporation of a single deuterium atom.^{8a} However, analysis of the

product revealed no deuterium incorporation (Scheme 1). Only when the reaction was carried out in CD₃CD₂OD was the incorporation of one D into the side chain observed (Scheme 1). On the basis of these findings, the reaction is proposed to occur via insertion of an alkene into a Pd hydride **C**, which is formed via Pd-catalyzed aerobic oxidation of the alcoholic solvent and thus stems from the alkyl chain of the alcohol (Figure 2A).^{9,10} This insertion reversibly forms Pd alkyl complexes **E** and **F**, of which **F** can proceed to form quinone methide intermediate **G**. This quinone methide undergoes nucleophilic attack to form the hydroalkoxylation product **4**. The reversible formation of both **E** and **F** is proposed based on the observation of **6a** and **6b** in the isotopic labeling experiments (Scheme 1).^{8a}

Although *o*- or *p*-vinylphenols are required in this reaction to access the quinone methide intermediate, we hypothesized that simple styrenes could undergo a similar reaction via a slightly different pathway (Figure 2B). In this paper, we describe the development of an alcohol oxidation coupled hydroalkoxylation of styrenes and several mechanistic experiments to probe the fundamental aspects of the reaction, which revealed that while an overall hydroalkoxylation reaction occurred, it proceeded via an unexpected benzylic chloride intermediate.

Results and Discussion

Reaction Development

As an initial experiment, the hydroalkoxylation of 4-methylstyrene was tested using conditions similar to those developed for vinyl phenols. It had been found previously that submitting simple styrene substrates to similar reaction conditions in an EtOH solvent led to acetal products,¹¹ and therefore, *i*PrOH, a much less nucleophilic alcohol that readily undergoes oxidation,¹² was selected as a solvent. Initially, 4-methylstyrene (**7a**) was chosen as the substrate, using Pd[(-)-sparteine]Cl₂ and CuCl₂ in *i*PrOH at 40 °C. Under these conditions, the desired hydroalkoxylation product was observed as the minor product, with the major product arising from Wacker oxidation (Scheme 2). Gratifyingly, the hydroalkoxylation product **8a** formed as a single regioisomer, which can be rationalized with the stabilization of **L** (as compared to **K**; see Figure 2B) via a π -benzyl Pd complex.¹³

With this initial result in hand, control experiments were performed, omitting either Pd or Cu to verify that both metals were required (Table 1, entries 2 and 3). Subsequently, the reaction conditions were optimized for the hydroalkoxylation product, the first steps of which are shown in Table 1. We hypothesized that the Wacker product likely arose from H₂O₂, which is formed as a byproduct of aerobic alcohol oxidation.¹⁴ Therefore, it was thought that the rate of alcohol

oxidation should be decreased to obtain high selectivities for the hydroalkoxylation product, so that ideally, every Pd hydride formed is incorporated into product. While the rate of alcohol oxidation could be decreased by lowering the concentration of the alcohol, *i*PrOH was also thought to be acting as the nucleophile, and lowering its concentration could potentially decrease the selectivity for the hydroalkoxylation product. Testing several different concentrations of *i*PrOH in 1,2-dichloroethane (DCE), 60% *i*PrOH in DCE was found to give the highest yield of hydroalkoxylation product (33%, Table 1, entry 4). Lowering the substrate concentration from 0.1 to 0.05 M, thus increasing the catalyst loading with respect to the substrate, led to an additional improvement (46%, Table 1, entry 5).

Further variation of the reaction conditions unfortunately did not lead to improvement in the reaction outcome. We therefore decided to evaluate other ligands on PdCl₂ and found that bathocuproine (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, bc) dramatically increased the reaction rate. However, when a time course of the reaction was performed by GC sampling, a significant induction period was observed (Figure 3, ▲).¹⁵ Bathocuproine is known to be a ligand for both Pd and Cu,^{12a,16} and thus, it was hypothesized that bathocuproine could be dissociating from the Pd complex during that induction period, with ligand-less Pd acting as the active catalyst. A separate time course was performed with preformed Cu(bc)Cl₂ rather than Pd(bc)Cl₂, mimicking the hypothesized catalyst mixture present after the induction period (Figure 3, ○). Upon performing the experiment, no induction period was observed when bathocuproine was bound to Cu instead of Pd prior to the start of the reaction. As a control, the reaction was performed with Pd-(MeCN)₂Cl₂ and CuCl₂ as well as with Pd(bc)Cl₂ and Cu(bc)-Cl₂. The latter reaction displayed a lower selectivity for the hydroalkoxylation product, while using ligand-less conditions led to decreased selectivity as well as a decreased reaction rate.¹⁷ From these experiments, it was concluded that improved selectivity and reaction rates were observed with a ligand on Cu rather than Pd, indicating that Cu was likely playing a more complex role than simply reoxidizing Pd⁰ to Pd^{II}, as is commonly proposed in Wacker-type oxidations.¹⁸

Additionally, upon switching to bathocuproine, a careful analysis of the reaction mixture showed the presence of an intermediate (Figure 4, ▲), which was identified as the benzylic chloride **10a**. On the basis of this observation, it was concluded that the active nucleophile is a chloride ion rather than *i*PrOH and that the hydroalkoxylation product likely arises from the benzylic chloride via an S_N1-type mechanism (vide infra). Considering that there is 4 times more CuCl₂ in the reaction mixture than PdCl₂, it is likely that CuCl₂ is the major source for that chloride. Overall, this is an interesting and unexpected finding since metal-catalyzed hydrochlorination reactions have not been observed previously.

Having gained some crucial insight into the reaction from the experiments detailed previously, further optimization was performed using Pd(MeCN)₂Cl₂ and a mixture of Cu(bc)Cl₂ and CuCl₂. Interestingly, a combination of 10 mol % Cu(bc)Cl₂ with 30 mol % CuCl₂ was optimal, giving a 47% GC yield of the hydroalkoxylation product (Table 2, entry 2), while 40 mol % Cu(bc)Cl₂ gave 15% hydroalkoxylation and 51% Wacker product (Table 2, entry 1). Assuming that the chloride intermediate (**10**) was converted to product via an S_N1-type reaction, the rate of this substitution should be independent of the concentration of *i*PrOH (apart from polarity effects), and *i*PrOH should influence the reaction mainly via the rate of alcohol oxidation (vide supra). When the concentration of *i*PrOH was further lowered to 10% *i*PrOH in DCE, the selectivity for the hydroalkoxylation product improved slightly to 49% GC yield (Table 2, entry 3). Subsequently, the temperature was raised to accelerate the nucleophilic substitution. This, in turn, would release more chloride and thus promote the formation of benzylic chloride **10**. Indeed, when the temperature was increased from 40 to 60 °C, the GC yield of the hydroalkoxylation product increased to 62% (Table 2, entry 4). Additionally, the amount of chloride in the reaction mixture was further raised by changing the loading of CuCl₂ from 30

to 40 mol %, leading to 84% GC yield of the desired product (Table 2, entry 5). Higher concentrations of CuCl₂ unfortunately inhibited the reaction, presumably due to slowing the rate of alcohol oxidation.¹⁹ Under these conditions, the catalyst loading could be reduced without substantial decrease in product yield (77% GC yield, Table 2, entry 6).

Having optimized the reaction for 4-methylstyrene, several other substrates were submitted to the reaction conditions. While electron-rich styrenes are excellent substrates, electron-poor styrenes gave mixtures of hydroalkoxylation and hydrohalogenation products along with increased amounts of Wacker products, illustrating the high sensitivity of the reaction to the electronic nature of the substrate. Interestingly, while 4-methylstyrene gave good yields of the hydroalkoxylation product, styrene was sufficiently electron-poor to yield the hydrochlorination product. For electron-poor substrates, the reaction was thus optimized for hydrochlorination by lowering the temperature to 50 °C, increasing the catalyst loading to the previous level (with 50 mol % CuCl₂), and decreasing the amount of *i*PrOH to 2.5% in DCE. Upon isolation, the hydrochlorination product was found to contain ca. 5% of the regioisomeric primary chloride (2-chloroethylarene), which was likely formed from the regioisomeric Pd alkyl complex (**K**, see Figure 1). This was entirely unexpected since no primary ether product had been observed with the electron-rich substrates. It is reasonable, however, that the primary chloride is reversibly formed in the reaction of electron-rich substrates but does not undergo the S_N1 reaction to produce the ether product.²⁰

Mechanistic Investigations. Conversion of Benzylic Chloride

The unexpected results obtained above prompted us to study the reaction in greater detail. Specifically, we wished to address the conversion of the benzylic chloride **10** to the ether, the roles of the different metals, and finally the origin of the proton incorporated into the product. To confirm that chloride **10** converted to the hydroalkoxylation product, **10a** was independently prepared and submitted to reaction conditions. Indeed, when **10a** was heated to 40 °C in *i*PrOH, it converted exclusively to the hydroalkoxylation product (**8a**). In the presence of metal catalysts, the reaction was significantly accelerated, possibly due to the metals acting as Lewis acid catalysts (Table 4). This information together with the fact that electron-poor benzylic chlorides do not convert completely to the ether product implies that a metal assisted S_N1 reaction is most likely occurring.²²

Deuterium Labeling Studies

To determine the origin of the proton incorporated into the product, several deuterium labeling experiments were performed. On the basis of precedents from our laboratory,^{8a} our initial hypothesis was that a Pd hydride was formed during *i*PrOH oxidation and that this hydride was subsequently incorporated into the product (vide supra). To confirm this, several deuterium labeling experiments were carried out, as shown in Figure 5.

Initially, two control experiments were performed in (CH₃)₂-CHOD and DCE-*d*₄ (Figure 5, eqs 4 and 5), to probe the involvement of the acidic proton or protons from the DCE solvent. As expected, no deuterium incorporation was observed in any of the products, thus strongly suggesting the absence of Brønsted acid catalysis. Subsequently, the reaction was performed in (CH₃)₂CDOH and (CD₃)₂CDOD, respectively (eqs 6 and 7). With both of these alcohols, deuterium incorporation into the double bond was expected since the Pd hydride would be formed in the β-hydride elimination step of the alcohol oxidation and thus would stem from the α-position of *i*PrOH.⁹ However, isotopic depletion could potentially occur via the enol form of acetone (the oxidation product of *i*PrOH) in the case of (CH₃)₂CDOH. With (CD₃)₂CDOD, any such exchange would be inconsequential.²³ Upon performing these experiments, very similar results were observed, in which two main isotopologues are formed. The major isotopologue containing 2 or 8 D, respectively, is consistent with the proton incorporated into

the side chain arising from alcohol oxidation and is formed in 48 and 46% yield (of the overall hydroalkoxylation product). However, another isotopologue with 1 (or 7) D was observed in 39 and 43% yield, which was initially unexpected. Closer investigation of the styrene substrate at early time points revealed partial D incorporation, and an isotopologue containing 3 or 9 D was observed in 11%. This D incorporation into substrate could arise from reversible alkene insertion/ β -hydride elimination (Scheme 3) and provides a pathway for D scrambling and potential isotopic depletion in the product.²⁴

To probe this, substrate **15** was prepared containing 3 D in the olefin (93% 3 D) and submitted to reaction conditions with (CH₃)₂CDOH or (CD₃)₂CDOD (eqs 8 and 9). As expected, significantly higher levels of isotopic incorporation were observed, consistent with the equilibrium shown previously. Specifically, the major isotopologue (containing 5 and 11 D, respectively) was formed in 74 and 81%, again indicating that no significant exchange via enol chemistry was occurring.

Additionally, it was found that the reaction using deuterated substrate **15** in (CH₃)₂CDOH or (CD₃)₂CDOD was significantly faster than that using nonlabeled material (**15** in (CH₃)₂CDOH: 43% conversion at 0.5 h; **7a** in *i*PrOH: 18% conversion at 0.5 h), indicating a large inverse isotope effect.¹⁷ This unusual finding indicates that alcohol oxidation is probably not rate limiting in the overall reaction since normal isotope effects have been measured for alcohol oxidation reactions under similar conditions.^{12a,25} It is plausible that the isotope effect originates in the equilibrium shown in Scheme 3. The relative equilibrium positions should depend on the differences in energy between Pd–D/C–D as compared to the Pd–H/C–H bond strength.²⁶ This could result in the equilibrium for the Pd–D lying further on the side of the Pd– π -benzyl complex. This would provide a higher concentration of the Pd π -benzyl complex and thus potentially accelerate the reaction, leading to an inverse equilibrium isotope effect.

Analysis of Alcohol Oxidation and Role of Metals

Having confirmed that alcohol oxidation is the source of the Pd hydride, we wanted to determine how many equivalents of alcohol were oxidized per equivalent of styrene converted. For these experiments, a heavier alcohol was selected, namely, 2-octanol, which shows similar results to *i*PrOH, for ease of detection by GC. Upon performing the experiment, it was found that 1.1 equiv of 2-octanone was formed per equivalent of styrene consumed. This confirmed our initial hypothesis that the rates of alcohol oxidation and alkene insertion/nucleophilic attack should be well-matched to achieve an efficient reaction. As an additional control to determine the role of the metal catalysts, 2-octanol was submitted to the reaction conditions omitting either Pd or Cu. Unfortunately, no alcohol oxidation occurred under those conditions, indicating that both metals were required for this transformation. It is likely that Cu^{II} (Cu(bc)Cl₂ and/or CuCl₂) is acting as a cooxidant for Pd⁰, as it does, for example, in Wacker oxidations.¹⁸ The role of each metal in the subsequent olefin functionalization could not be tested since the Pd hydride required for the reaction was not formed in the absence of either. It seems logical, however, that CuCl₂ and/or Cu(bc)Cl₂ is acting as a chloride source to form benzylic chloride **10**. To test this, and potentially distinguish the roles of the two Cu species, CuCl₂ and Cu(bc)Cl₂ were separately substituted by Bu₄NCl.¹⁷ In both cases, mainly the product of a Wacker oxidation is observed (**9**), indicating that neither CuCl₂ nor Cu(bc)Cl₂ can simply be replaced by other chloride sources. The specific roles of ligated and nonligated CuCl₂ unfortunately cannot be distinguished at this point.

Proposed Mechanism

On the basis of the information obtained from the isotopic labeling experiments, the observation of the chloride intermediate, and the other experiments shown previously, the mechanism shown in Figure 6 is proposed. Initially, Pd hydride **N** is formed via an alcohol oxidation, which

is supported by the isotopic labeling experiments as well as the observed oxidation of 2-octanol. The styrene substrate is then coordinated to Pd, followed by insertion of the double bond into the Pd hydride. The observed incorporation of deuterium into the styrene indicates both the coordination and the insertion steps are reversible. On the basis of the observation of the primary chloride byproduct with electron-poor styrenes, it is assumed that both Pd alkyls **P** and **Q** are formed, as observed in the hydroalkoxylation of vinylphenols. However, **Q** can be stabilized via a π -benzyl intermediate and thus is likely formed predominantly. In the following step, chlorides **10** and **20** are formed, either via reductive elimination or nucleophilic attack on **P** or **Q**, respectively, by an exogenous chloride ion.²⁷ In either case, Pd^{II} is reduced to a Pd⁰ species (**R**), which is subsequently reoxidized by O₂ and/or CuCl₂. Additionally, H₂O₂ (formed in situ) has been shown to be a competent oxidant to form Pd^{IV} intermediates,³⁰ and reductive elimination of C–Cl bonds from Pd^{IV} has been observed previously.³¹ In the case of electron-rich aromatic systems, the benzylic chloride is transformed into the ether product **8** via a metal promoted S_N1 reaction, while in the case of more electron-poor aromatic substrates, the rate of this step is slow enough to allow for isolation of the chloride. A competing mechanism involving direct substitution of Pd by *i*PrOH as proposed in Figure 1B cannot be ruled out at this time. However, on the basis of the isolation of the chloride product from electron-poor styrenes and the time course showing its conversion to the hydroalkoxylation product, the mechanism shown in Figure 6 is proposed to be dominant.

Conclusion

In this paper, the development of Pd-catalyzed hydrohalogenation of styrenes, followed by a substrate dependent in situ S_N1 reaction to form benzylic ethers, is disclosed. On the basis of isotopic labeling experiments, the proton incorporated into the substrate is proposed to originate from a Pd hydride formed via a Pd-catalyzed aerobic alcohol oxidation. The most exciting aspect of this transformation is this unique mechanistic motif, which contrasts with the typical use of acidic conditions in many other hydrofunctionalization reactions of olefins. Therefore, future efforts to develop new olefin hydrofunctionalization reactions in our laboratory will seek to expand the concept of coupling Pd-catalyzed aerobic alcohol oxidations.

Experimental Procedures

General Information

DCE was distilled from CaH₂, and *i*PrOH was dried by refluxing over CaO for 12 h followed by fractional distillation. Styrene substrates were purified by passing through a small plug of activated neutral alumina before use. The 3 Å molecular sieves were powdered and activated by heating with a Bunsen burner under vacuum. ¹H NMR spectra were obtained at 300 MHz and referenced to the residual CHCl₃ singlet at 7.26 ppm. ¹³C NMR were obtained at 75 MHz and referenced to the center line of the CDCl₃ triplet at 77.23 ppm. Flash column chromatography was performed using EM Reagent silica 60 (230–400 mesh). GC/MS spectra were obtained on a HP 5890 (EI) 20:1 split. HRMS spectra were obtained on an Agilent LCTOF. Caution should be taken when heating flammable solvents in the presence of O₂.

General Procedure for Hydroalkoxylation of Electron-Rich Styrenes (**8a**)

Into an oven-dried 100 mL Schlenk flask equipped with a stirbar were added 13.0 mg of Pd (MeCN)₂Cl₂ (0.0500 mmol, 0.0500 equiv), 24.7 mg of Cu(bc)Cl₂ (0.0500 mmol, 0.0500 equiv), 26.8 mg of CuCl₂ (0.200 mmol, 0.200 equiv), and 500 mg of freshly activated crushed 3 Å molecular sieves. A condenser was placed on the flask, and the joint was lightly greased and wrapped with Teflon tape to ensure a good seal. DCE (18.0 mL) followed by *i*PrOH (2.00 mL) was added, and a three-way adapter fitted with a balloon of O₂ was placed on the condenser. The flask was evacuated via water aspiration and refilled with O₂ 3 times while

being stirred. The orange mixture was then stirred under O₂ at room temperature for 30 min, and 118 mg of 4-methylstyrene (**7a**, 1.00 mmol, 1.00 equiv) was added via syringe. The reaction mixture was placed in an oil bath at 60 °C and stirred under O₂ for 24 h. During this time, the mixture turned from orange to brown and back to orange. After 24 h, the mixture was cooled to room temperature and passed through a large plug of silica (ca. 8 g) with 100 mL of 1:1 Et₂O/hexanes. The solvent was removed in vacuo to obtain an orange oil. This was mixed with 10.0 mL of hexanes and washed with saturated aqueous NaHCO₃ (3 × 10.0 mL). The combined aqueous layer was then extracted with hexanes (2 × 10.0 mL). The combined organic layers were dried over MgSO₄, and the solvent was removed in vacuo. The resulting pale yellow oil was purified via flash column chromatography by eluting with hexanes → 1% Et₂O/hexanes → 3% Et₂O/hexanes. The product (**8a**) was obtained as a clear oil (98.4 mg, 0.552 mmol, 55% yield). ¹H NMR (300 MHz, CDCl₃) δ 1.09 (d, *J* = 6.3 Hz, 3 H), 1.14 (d, *J* = 6.0 Hz, 3 H), 1.39 (d, *J* = 6.3 Hz, 3 H), 2.34 (s, 3 H), 3.48 (qq, *J* = 6.0 Hz, 6.3 Hz, 1 H), 4.50 (q, *J* = 6.3 Hz, 1 H), 7.12 – 7.24 (m, 4 H); ¹³C NMR {¹H} (75 MHz, CDCl₃) δ 21.3, 21.5, 23.6, 25.0, 68.5, 74.6, 126.2, 129.2, 137.0, 142.0; MS (ESI/APCI) *m/z* (MNH₄⁺) calcd: 196.1701; obsd: 196.1693.

General Procedure for Hydrochlorination of Electron-Poor Styrenes (**10e**)

Into an oven-dried 100 mL Schlenk flask equipped with a stirbar were added 25.9 mg of Pd (MeCN)₂Cl₂ (0.100 mmol, 0.100 equiv), 49.5 mg of Cu(bc)Cl₂ (0.100 mmol, 0.100 equiv), 67.1 mg of CuCl₂ (0.500 mmol, 0.500 equiv), and 1.00 g of freshly activated crushed 3 Å molecular sieves. A condenser was placed on the flask, and the joint was lightly greased and wrapped with Teflon tape to ensure a good seal. DCE (19.5 mL) followed by *i*PrOH (0.500 mL) was added, and a three-way adapter fitted with a balloon of O₂ was placed on the condenser. The flask was evacuated via water aspiration and refilled with O₂ 3 times while stirring. The orange mixture was then stirred under O₂ at room temperature for 30 min. A total of 139 mg of 4-chlorostyrene (1.00 mmol, 1.00 equiv) was then added via syringe, and the reaction mixture was placed in an oil bath at 50 °C. The reaction mixture was stirred under O₂ for 28 h. During this time, the mixture turned from orange to dark brown. After 28 h, the mixture was cooled to room temperature and passed through a large plug of silica (ca. 8 g) with 100 mL of 1:1 Et₂O/hexanes. The solvent was removed in vacuo to obtain a clear oil. The oil was purified by flash column chromatography by eluting with hexanes → 1% Et₂O/hexanes → 5% Et₂O/hexanes → 10% Et₂O/hexanes. The product (**10e**) was obtained as a clear oil (60.8 mg, 0.347 mmol, 35% yield; containing 6% primary chloride by NMR). ¹H NMR (300 MHz, CDCl₃) δ 1.83 (d, *J* = 6.87 Hz, 3 H), 3.04 (t, *J* = 7.42 Hz, 0.12 H), 3.70 (t, *J* = 7.42 Hz, 0.13 H), 5.06 (q, *J* = 6.87, 1 H), 7.30–7.38 (m, 4 H); ¹³C NMR {¹H} (75 MHz, CDCl₃) δ 26.7, 58.0, 128.1, 129.0, 134.2, 141.5; GC/MS: (*m/z*) calcd: 174.00; obsd: 173.90 [M]⁺, 139.00 [M – Cl]⁺.

24. D incorporation into styrene could not be quantified due to the loss of H (D) in the mass spectrometer. Additionally, different product ratios were observed for reactions involving deuterated alcohol and/or styrene, and deuterium incorporation was observed in the Wacker product, which should originate from deuterated styrene.

Deuterium Labeling for Hydroalkoxylation of Vinylphenols

Figure 2. Proposed mechanism for hydroalkoxylation of vinylphenols (A)^{8a} and hypothesis for hydroalkoxylation of styrenes (B).

Scheme 2.
Initial Discovery of Hydroalkoxylation of Styrenes

Figure 3.

Time course of hydroalkoxylation with Pd(bc)Cl₂ and Cu(bc)Cl₂. ^aCondition A: 10 mol % Pd(bc)Cl₂, 40 mol % CuCl₂, 3 Å molecular sieve, 60% *i*PrOH/DCE, 40 °C, balloon O₂. Condition B: 10 mol % Pd(MeCN)₂Cl₂, 10 mol % Cu(bc)Cl₂, 30 mol % CuCl₂, 3 Å molecular sieve, 60% *i*PrOH/DCE, 40 °C, balloon O₂.

Figure 4.
Time course of hydroalkoxylation showing chloride intermediate.

Figure 5.
Deuterium labeling studies.

Scheme 3.
Reversible Alkene Insertion/ β -Hydride Elimination

Figure 6.
Proposed mechanism of hydrohalogenation/hydroalkoxylation of styrenes.

Table 1

Initial Optimization of Hydroalkoxylation Reaction

entry	X	5 (mol %)	CuCl ₂ (mol %)	conversion ^a (%)	8 ^a (%)	9 ^b (%)
1	100	5	20	92.4	19	52
2	100	0	20	<5		
3	100	5	0	<5		
4	60	5	20	>99	33	41
5 ^c	60	10	40	>99	46	40

^a Determined via GC analysis using an internal standard.^b Determined via GC analysis using an internal standard and response factors.^c 0.05 M in substrate.

Table 3
Scope of Hydrochlorination/Hydroalkoxylation Reaction

entry	substrate	cond.	product	yield (%)
1	7a	A	8a	55
2	7b	A	8b	73
3	7c	A	8c	78
4	7d	B	10d	22 ^b
5	7e	B	10e	44 ^b

^a Condition A: 5 mol % Pd(MeCN)₂Cl₂, 5 mol % Cu(bc)Cl₂, 20 mol % CuCl₂, 0.5 g/mmol 3 Å molecular sieve, 10% *i*PrOH/DCE, 60 °C, O₂ balloon.
Condition B: 10 mol % Pd(MeCN)₂Cl₂, 10 mol % Cu(bc)Cl₂, 50 mol % CuCl₂, 1.0 g/mmol 3 Å molecular sieve, 2.5% *i*PrOH/DCE, 50 °C, O₂ balloon.

^b Including ca. 5% regioisomer (primary chloride).

Table 4

Promotion of Conversion of 10a to 8a by Different Additives

entry	additive	time (h)	% conversion ^a	% 8a ^b
1		22.5	30	29
2	1 g/mmol 3 Å molecular sieve	22.5	39	38
3	10 mol % Cu(bc)Cl ₂ , 30 mol % CuCl ₂ , 1 g/mmol 3 Å molecular sieve	15.5	79	73
4	10 mol % Pd(MeCN) ₂ Cl ₂ , 1 g/mmol 3 Å molecular sieve	15.5	67	62
5	10 mol % Cu(bc)Cl ₂ , 30 mol % CuCl ₂ , 10 mol % Pd (MeCN) ₂ Cl ₂ , 1 g/mmol 3 Å molecular sieve	15.5	91	85

^aDetermined via GC analysis using an internal standard.^bDetermined via GC analysis using an internal standard and response factors.
