Abstract

Aggression after traumatic brain injury (TBI) is common but not well defined. Sixty-seven participants with first-time TBI were seen within three months of injury and evaluated for aggression. The prevalence of aggression was found to be 28.4% and to be predominantly verbal aggression. Post-TBI aggression was associated with new-onset major depression ($p=0.02$), poorer social functioning ($p=0.04$), and increased dependency on activities of daily living ($p=0.03$), but not with a history of substance abuse or adult/childhood behavioral problems. Implications of the study include early screening for aggression, evaluation for depression, and consideration of psychosocial support in aggressive patients.

Introduction

Aggression is one of the most common consequences of traumatic brain injury (TBI). Prevalence estimates of post-TBI aggression range from 11%¹ to 34%,² likely due to differing samples and definitions. However, the phenomenology of post-TBI aggression is not yet well defined.³ Aggression may manifest as verbal and/or physical aggression, but it is unclear if differing expressions of aggression are distinct syndromes or if it constitutes a continuum of symptoms. Understanding the phenomenology and expressions of aggression in post-TBI aggression may help investigators with treatment and prevention. Post-TBI aggression may be a symptom of delirium, mood disorder,⁴ or 'personality change'

secondary to TBI.³ Aggression interferes with rehabilitation and is a major cause of burden both to the patient and caregivers.⁵ Understanding of the correlates and predictors of aggression may provide important clues for the prevention and treatment of post-TBI aggression, thus improving the rehabilitation potential in the crucial early post-TBI period.

Prior studies have shown that post-TBI aggression is correlated with depression, frontal lobe lesions, poor pre-TBI psychosocial functioning, and a history of alcohol and substance abuse.^{2,6-8} However, most of these studies focused on subjects who were several months to years post TBI. There is only one published study of aggression in the first three months after injury, which reported that severe TBI patients had cognitive and behavioral problems but not emotional problems when compared to mild-moderate TBI patients.⁷ In the current study, we present preliminary cross-sectional findings on the prevalence and correlates of aggression within three months of TBI in participants who are not delirious. We hypothesized that (1) aggression would be common after TBI, (2) aggression would include both verbal aggression and physical aggression, and (3) correlates of aggression would include major depression, substance abuse, and adult/childhood behavior problems.^{2,3}

We sought to examine aggression in the first three months of TBI and characterize its severity and association with psychiatric diagnoses in adults with first time closed-head injury. This study is part of a larger ongoing study to determine prevalence and risk factors associated with the development of psychiatric disorders after TBI. The results presented here are thus preliminary.

Methods

We performed an observational prospective study of the prevalence of aggression in the three months following TBI in a cohort of participants recruited within three months of trauma. We assessed the prevalence and subgrouping of aggression symptoms. We then examined the correlates of post-TBI aggression in a nested case-control design.

Participants & Procedures

A total of 107 subjects with first-time closed head injuries were recruited within three months of trauma from the acute trauma unit of the Johns Hopkins Hospital and the Brain Injury (rehabilitation) unit of Kernan Hospital, University of Maryland. Evaluations were completed only on participants able to give informed consent; we evaluated the ability of participants to give informed consent based on their treating physicians' opinions and based on the abilities of the participants to accurately summarize the study and their roles in it. All participants received two study evaluations within three months of the TBI. The first evaluation (V0) was done to assess lifetime history of psychiatric problems and pre-TBI psychosocial functioning in those participants who were able to provide written informed consent within the first two weeks of trauma. The second evaluation (V1) for these participants was done approximately three months post-TBI to assess psychiatric problems and psychosocial functioning after TBI. However, for participants who were unable to give consent within the first two weeks post-TBI, both the pre-TBI and post-TBI status were assessed at the time they were able to provide informed consent; within the three months post-TBI (i.e. for these participants, V0 and V1 data were collected at a single visit corresponding to the V1 visit). Information from a collateral informant was collected whenever possible on both the pre-TBI and post-TBI status on all psychosocial measures.

Of the 107, forty participants did not return for the follow-up visit and were therefore excluded from this analysis. Of the 40 excluded, 25 could not be contacted because of incorrect address and telephone numbers, 8 refused to participate, 5 had unstable medical problems, 1 was incarcerated, and 1 had anoxic brain injury.

For the purposes of the study, TBI was defined as having *at least one of the following*: (a) clear history of loss of consciousness; (b) Glasgow Coma Score less than 15; and/or (c) evidence of trauma (contusion or hemorrhage) on computerized tomography (CT) scans done as part of clinical workup. Other inclusion criteria included: (a) ability to provide consent personally, (b) ≥ 18 years of age, and (c) admission to the hospital for evaluation of head trauma. Exclusion criteria included (a) prior TBI; (b) an open-head injury (e.g. a displaced skull fracture or a gun shot wound); or (c) a history of any other type of brain illness (e.g. stroke, seizure, encephalitis). The study was approved by the Institutional Review Board of both universities.

Measures

All measures were administered by a neuropsychiatrist (VR) except the cognitive tests, which were administered by the study research coordinators (JS and MB).

Aggression—The Overt Aggression Scale⁹ (OAS) was used to assess verbal and physical aggressive behavior. The OAS has two sections. The first assesses four types of aggressive behavior: (1) verbal aggression, (2) physical aggression against objects, (3) physical aggression against self, and (4) physical aggression against others. The severity of each subtype can be rated using a weighted score: verbal aggression (1-4 points), physical aggression toward objects (2-5 points), physical aggression toward self (3-6 points), and physical aggression toward others (3-6 points), with a range of 0-21 for total OAS score. The second section rates interventions provided by staff at the time of the incident. As the focus of the study is to assess prevalence and correlates of aggression after TBI, only the first section of the scale was administered at V1. The OAS has been validated in adult and pediatric inpatients with neuropsychiatric illness and violent behavior.¹⁰⁻¹² Other researchers have also noted significant correlation between the OAS aggression and Aberrant Behavior Checklist Community Scale irritability subscale, in a study of outpatient youths with aggression.¹³

Psychiatric Diagnoses—Axis 1 psychiatric diagnosis was determined using the Structured Clinical Interview for DSM-IV Axis 1 disorders (SCID-I)- Clinician Version.¹⁴ Diagnoses such as Impulse Control Disorder and Intermittent Explosive Disorder, which are probably relevant to TBI-aggression, were not obtained because the SCID-I does not contain these diagnoses.

Severity of TBI—The severity of TBI was determined by the Glasgow Coma Scale (GCS), the most widely used instrument for quantifying TBI severity. The GCS is administered by the trauma staff or the emergency room personnel in their initial evaluation, and has a range of 3-15. GCS scores of 3-8 are considered severe TBI, 9-12 moderate TBI, and 13-15 mild TBI.¹⁵ All those determined to have mild TBI, as defined by GCS, also met the mild TBI (MTBI) criteria of the American Congress of Rehabilitation.¹⁶ The American Congress of Rehabilitation Medicine (ACRM) defines mild TBI as traumatically induced physiological disruption of brain manifested by a least one of the following: (a) any period of loss of consciousness; (b) any loss of memory for events immediately before or after the accident; (c) any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused); and (4) focal neurological deficit(s) that may or may not be transient. However, the duration of post-traumatic amnesia should not be greater than 24 hours, the duration of loss of consciousness not exceed 30 minutes, and the initial Glasgow Coma Scale (GCS) score should range from 13-15 after 30 minutes post-injury.

Medical Co-morbidity—Medical comorbidity was assessed using the General Medical Health Rating (GMHR) scale.¹⁷ The GMHR, which ranges from 1 (poor health) to 4

(excellent health), provides a global assessment of a person's medical problems and medications. Data on the number of medications used by each patient were collected but not the type of medications.

Psychosocial Functioning—Participants' pre and post-TBI psychosocial functioning was assessed using the Social Functioning Exam (SFE) and Social Ties Checklist (STC).¹⁸ Both these scales have been used in prior TBI studies.^{19,20} Scores on the SFE and STC range from 0 (greatest satisfaction) to 1 (least satisfaction). The reliability and validity of these instruments have been demonstrated in people with brain injury.²¹

Family History of Psychiatric Illness—Family history of psychiatric illness was assessed using the Family History Screening instrument.²²

Behavior & Legal Problems—Pre and post-TBI behavior and legal problems were also analyzed. Childhood behavioral problems were defined by the presence of two or more of the following: suspension from school, expulsion from school, setting fires, cruelty to animals, and/or destroying property. Adult behavioral problems were defined as being fired from work, fights, or violent behavior that interfered with interpersonal relationships, occupational, or social life. Legal problems were defined as the presence of one or more of the following: arrests, incarcerations, jailed or being placed on parole or probation. Both pre and post-TBI legal status were included in the assessment.

Cognitive Tests—Neuropsychological tests were administered to all study participants at V1. The battery consisted of: Mini Mental State Examination (MMSE);²³ National Adult Reading Test;²⁴ Verbal fluency (letter 's' and 'p') and category (animals & supermarket);²⁵ Hopkins Verbal Learning Test-Revised;²⁴ Brief Visuospatial Memory Test-Revised;²⁷ Trail Making Test;²⁸ Stroop Color and Word Test;²⁹ Brief Test of Attention;³⁰ and the Wisconsin Card Sorting Test.³¹

Neuroimaging—All participants had computerized tomography (CT) head scan done as part of routine clinical care. CT results were categorized as presence or absence lesions in different brain regions (i.e. right, left, bilateral frontal, temporal, parietal, occipital, sub-cortical).

Data Analysis

Participants were categorized as having "aggression" if they endorsed any of the subtype anchor questions on the OAS. Those who endorsed a screening question for a particular subtype were then asked follow-up questions to quantify the severity of aggression on that subtype.

Descriptive statistics were calculated for all participants and for subgroups stratified by post-TBI aggression status. The significance of group differences (two-tailed) on individual variables were compared using Pearson's chi-square and Fisher's exact test for categorical variables and Students' t-test for continuous variables. The criterion for statistical significance was set at $p < 0.05$.

To assess the strength of the relationship between aggression and the demographic and clinical factors, we conducted univariate logistic regression analysis with presence/absence of aggression as the dependent variable. On comparison of the two groups, those variables that were statistically significant and those that trended towards significance were included as independent variables in the univariate regression analyses. Significance levels were set at $p < 0.05$.

Results

A total of 107 participants who met the study inclusion/exclusion criteria were enrolled at V0. Of these, only those who had the first follow-up visit (i.e. only those with data for V1) ($n = 67$) were included in this analysis. Forty participants ($n = 40$) were excluded from the analysis as they did not have a V1 visit 1-3 months post injury.

There were no significant differences between those with V1 data and those without V1 data in age, gender, severity of TBI, nature of TBI, income, race, marital or living situation, pre-TBI depression, and pre-TBI alcohol or substance abuse problems. The only significant difference was that the majority of participants without V1 data had a normal head CT (80% versus 53.7%; $p=0.007$).

Sample Demographics

Table 1 provides the demographic description of the sample. Motor vehicle accident (53.7%) was the most common cause of TBI followed by falls (22.4%) and assaults (22.4%). Mild TBI (GCS score of 13-15) was seen in 59.7% of the sample, moderate TBI (GCS score 9-12) in 13.4%, and severe TBI (GCS score <9) in 26.9%. All patients were ambulatory and medically stable. Only 9% had a GMHR score of 1 (poor health: several unstable medical problems), 21% had a score of 2 (fair health: more than one unstable medical conditions and/or several stable but chronic medical problems), 40% had a score of 3 (Good: one unstable medical problem or few stable medical problems) and 30% had a score of 4 (Excellent: no current unstable medical problems).

Prevalence and symptoms of aggression (Tables 2 and 3)

The prevalence of aggression was found to be 28.4%. Verbal aggression (28.4%) was the most prevalent subtype of reported aggression in the post-TBI period. Only one participant displayed both verbal aggression and physical aggression against objects. No participants displayed aggression against self or others. The two most common symptoms of verbal aggression included angry shouts and vicious cursing with moderate threats of violence. As verbal aggression was the most common type of aggression, subsequent analyses examine solely verbal aggression as an outcome.

Comparison of participants with and without aggression on demographic and injury variables

There were no statistically significant differences on demographic and injury variables between participants with and without aggression in the post-TBI period. However, female gender was associated with aggression, trending towards statistical significance ($p=0.055$) (Table 4). In addition to comparing the two groups on the GCS, the groups were also compared on the duration of loss of consciousness, but no significant differences were noted between those with and without aggression. (Table 5). Similarly, there was also no significant difference on the OAS between those with mild TBI and moderate/severe TBI ($t=1.18$; $df=17$; $p=0.25$).

Comparison of participants with and without aggression on clinical variables

Participants with aggression in the post-TBI period had a higher prevalence of new-onset major depression in the post-TBI period (mood disorder due to general medical condition, major depression like episode, MDGMC) ($p=0.02$). No group differences were observed for any other Axis 1 psychiatric diagnoses, including pre-TBI depression and post-TBI major depression, recurrent. Those with aggression were also more likely to have poorer social functioning ($p=.04$) and increased dependence on personal and instrumental activities of daily living as assessed by the Lawton Activities of daily living scale³³ ($p=0.03$) (Table 6).

Similarly, there were no differences between those with and without aggression on pre-TBI or post-TBI history of alcohol or substance abuse, pre or post-TBI legal problems, pre- or post-TBI history of adult behavior problems and childhood behavior problems.

There was no significant difference between the two groups on cognitive tests (Table 7) or head CT abnormalities (Table 4).

To determine if new-onset major depression in the post-TBI period (MDGMC), psychosocial impairment, and increased dependence on activities of daily living was associated with injury related medical problems, we compared those with and without body injury on these three variables. Body injury was associated with increased dependence on activities of daily living ($t=3.29$; $df=64$; $P=.002$), but not with psychosocial impairment ($t=-.149$; $df=64$; $P=.88$) or MDGMC ($X^2=.56$; $df=1$; $P=.69$).

Correlates of post-TBI aggression (Table 8)

Univariate logistic regression was conducted with presence/absence of aggression as the dependent variable. The presence of psychosocial impairment post-injury was found to increase the odds of aggression in the post-TBI period 62-fold ($OR=62.4$; 95% CI =1.32-2957.42), diagnosis of MDGMC increased the odds 8-fold ($OR=8.2$; 95% CI =1.43 – 47.06), and increased dependence on activities of daily living increased the risk by 8% ($OR=1.08$; 95% CI =1.006-1.164). No other correlates attained statistical significance.

Discussion

In a nested case-control study of TBI patients during the first three months following injury, we found that verbal aggression was quite prevalent but physical aggression was virtually absent. Aggression in the post-TBI period was associated with impaired post-TBI psychosocial functioning, new-onset major depression post-TBI, and increased dependence on activities of daily living. Interestingly enough, recurrence of pre-TBI major depression was not a predictor of aggression.

We report several significant negative findings. Only one of the 67 participants exhibited physical aggression, and this was in a milder form (aggression only toward objects). None exhibited physical aggression towards self or others. We observed no significant association between post-TBI aggression and several covariates reported in prior studies including childhood behavior problems, adult behavior problems, legal charges, pre or post-TBI substance abuse or dependence, neuropsychological tests or brain lesions.

The prevalence of aggression is similar to what is reported in the literature,^{2,8} as is the mix of TBI severity with approximately 60% having mild TBI.³² On reviewing the literature on the subtypes of aggression after brain injury, several studies have noted an association between brain injury and physical aggression.³⁴⁻³⁷ Only one person reported to history of physical aggression in our study. Our findings are consistent with anecdotal reports on the predominance of verbal aggression after TBI.^{38,39} Dyer et al.³⁸ have also noted a higher prevalence of verbal aggression rather than physical aggression in a sample of TBI patients studied six months post-injury. This discrepancy in the literature could be due to differences in the definition of aggression, severity of TBI, and duration since TBI. Another possibility is that TBI aggression occurs in two forms: mild verbal aggression associated with mood disorder but not with pre-injury or post-injury behavior problems, and severe physical aggression which can be more complex and associated with significant behavior and legal problems.

We did however, observe that aggression was strongly associated with new-onset major depressive episodes which increased the risk of aggression by 8-fold, but not with recurrent major depression. Possibly new-onset depression after TBI is a phenotypic variant of idiopathic major depression with verbal aggression as a presenting symptom. Several other studies^{2,8} have also noted a significant association between depression and aggression but none of them have separated post-TBI depression as new-onset depression and recurrent depression. This is one of the strengths of our study.

Many researchers have also noted a relationship between aggression and pre-morbid characteristics such as childhood behavior problems,⁶ adult behavior difficulties, legal problems⁴⁰ and substance abuse.^{2,41} However, we did not observe these associations in our cohort. All prior studies have examined global aggression combining both verbal and physical aggression. The lack of an association in our study could be because our study observed only verbal aggression, which is likely to reflect a milder form of aggression than physical aggression. Thus, it is possible that mild (verbal) aggression is associated with post-TBI depression, while more severe (physical) aggression may be associated with adult and childhood behavioral problems and substance abuse. Our finding of the relationship between female gender and aggression (that trended towards statistical significance) was unexpected but not surprising, given our findings of a positive relationship between aggression and depressive syndrome. It is well known that females are at higher risk of developing major depression,⁴² though this has not been established for TBI cohorts.

Our study also found a significant association between verbal aggression and post-TBI social impairment. Baguley et al.⁸ have also noted a significant association between poor satisfaction with life and aggression 6 and 24 months post-TBI. This is not surprising as one might well predict that aggression would be interfering with relationships and reintegration into the community. However, the increased risk of aggression in persons with poor social functioning is quite remarkable (62-fold increased), even higher than that of depression. This finding has significant therapeutic implications for the immediate post-TBI period, suggesting the particular importance of improving psychosocial support, strengthening social connections, and providing adequate resources via individual, group and family therapy in reducing aggression. Studies have shown that psychosocial support and positive interpersonal relationships play an important role in reducing aggression.⁴³ An alternative explanation for our results is that early diagnosis and appropriate treatment of aggression might lead to better social and inter-personal functioning.

The significant association between aggression and increased dependence in activities of daily living has been reported before.⁴⁴ One possibility is that persons with TBI are resistant to assistance provided by their caregiver, perceiving assistance as an invasion of personal space. It is also possible that aggression may be associated with lack of motivation in the context of post-TBI depression with concomitant lack of interest in self-care and help from care providers. Alternatively, aggression may only be a confounder as our results showed that those with body injuries were more likely to have increased dependency on activities of daily living.

The literature suggests potential brain mechanisms for post-TBI aggression. Tateno et al.² found frontal lesions to be associated with aggression and suggest that frontal lobe injury can cause damage to the ascending serotonergic pathways, which can contribute to the pathophysiology of both depression and violent behavior. As systematic analysis of neuroimaging data was not part of our study, we are unable to comment on this possibility. However, we found no significant difference between those with and without aggression on CT head scans, performed as part of clinical work up. Similarly, we also did not find any group differences on neuropsychological tests, and more specifically, on tests particularly

sensitive to frontal functioning system. Starkstein and Robinson⁴⁵ have pointed out TBI aggression is probably secondary to loss of balance between inhibitory pathways in the prefrontal cortex and excitatory limbic structures that mediate mood. These mechanisms could explain our finding of an association between aggression and new-onset depression in the immediate post-TBI period. More sensitive neuroimaging tools such as functional MRI or diffusion tensor imaging scans may shed light on the brain mechanisms underlying TBI aggression.

Our findings do not prove that the aggression in the post-TBI period observed in our subjects was caused by the TBI, nor that any association was due to the biological effects of brain injury. For example, body injury was associated with increased dependence in ADLs which was further associated with aggression. It is possible that body injury could be an important mediator of aggression in the population, but the small sample size did not allow for systematic assessment of mediators and interactions. Similarly, the lack of association between TBI severity and aggression suggests the possibility that other factors than TBI are responsible for aggression; conversely, it could also suggest that TBI itself (rather than TBI severity) is an important risk factor for aggression. The lack of control groups with exposure to non-TBI bodily injuries and/or no injury is a limitation in addressing these issues. Other limitations of the study include the assessment of a narrowly defined cohort of TBI patients. Our study sample included only those with first time closed head injury, clear history of loss of consciousness, and those who were hospitalized. These strict inclusion/exclusion criteria may limit generalizability. Further, medication data was not available, precluding any study of the association between medications and aggression. Antipsychotics, benzodiazepines, antidepressants, and opioid analgesics are often used in the acute TBI period and might be effective treatments for severe agitation, which could account for the absence of physical aggression in our cohort. Systematic analysis of brain imaging data was also not performed, and thus we were unable to assess the association of exact lesion location and aggression. Finally, aggression was assessed only once in the acute TBI period by self-reports which is often associated with under-reporting and minimization of symptoms. However, whenever collateral informants were available, the subjects' history was always corroborated.

To the best of our knowledge, this is the second published study examining aggression in non-delirious patients within the first three months of TBI. Our finding of a significant association between poor psychosocial functioning and verbal aggression underscores the point that psychosocial support is an important aspect of emotional recovery and therefore should be an integral part of rehabilitation. Our preliminary finding that incident new-onset major depression after TBI, but not recurrent major depression, is associated with post-TBI aggression is novel and may have substantial implications for the phenomenology and treatment of post-TBI aggression.

Conclusion

Aggression in the acute TBI period is common. It is predominantly verbal, characterized by anger and threats of violence rather than physical aggression. Significant correlates include impaired psychosocial functioning and new-onset major depression. Implications of the study include early screening for aggression, evaluation for depression and consideration of psychosocial support in patients with aggression, and education of care providers regarding the frequency of post-TBI aggression. Future studies should focus on effective interventions to reduce aggression and improve psychosocial functioning.

Table 1

Sample (N=67) Demographics.

Variables	Results
Mean age in years (SD)	42.6 (17.7)
Male gender N (%)	41 (61.2%)
Mean education level in years (SD)	13.1 (2.9)
Full or part-time employed prior to TBI	51 (76.1%)
Married or presence of partner prior to TBI	44 (65.7%)
Annual Income >\$20K	38 (56.7%)
Non-Caucasian race N (%)	31 (46.3 %)

Table 2

Prevalence of subtypes of aggression

Variable	Frequency N (%)
Verbal Aggression	19 (28.4)
Physical Aggression against self	0
Aggression against objects	1 (1.5)
Aggression against others	0

Table 3

Symptoms of verbal aggression

Symptom	Frequency (%)
Makes loud noises, shouts angrily,	9 (47.4)
Yells mild insults	2 (10.5)
Curses viciously; moderate threats to self/others	8 (42.1)
Clear threats of violence towards self or others	0

Table 4

Comparison of those with and without aggression on demographic and injury variables

Variables	Aggression (N=19)	No Aggression (N=48)	df	p=
Age	42.1 (18.6)	42.9 (17.5)	.16	0.88
Education	13.1 (2.9)	13.1 (3.0)	.06	0.97
Female Gender	11 (57.9)	15 (31.3%)	X ² =.05	1 0.055
Race (Caucasian)	13 (68.4%)	22 (46.8%)	X ² =.11	1 0.17
Living with Others	16 (84.2%)	39 (84.8%)	FET	1.00
Married/Partner	11 (57.9)	33 (68.8)	X ² =.39	1 0.41
Working PT/FT	14 (73.7)	37 (77.1)	FET*	0.76
Religion	18 (94.7)	39 (83.0)	FET	0.43
Glasgow Coma Scale	11 (4.1)	12.7 (3.3)	1.7	.10
Cause of injury: motor vehicle accidents	12 (63.2)	24 (50)	X ² =1.37	3 .71
Body Injury Present	13 (68.4%)	28 (58.3%)	X ² =.45	0.58
Presence of any lesion on head scan	8 (42.1)	23 (47.9)	X ² =.67	1 0.79
Frontal Cortex Lesion	9 (47.4)	20 (41.7)	X ² =.67	1 0.79
Temporal Cortex Lesion	3 (15.8)	10 (20.8)	FET	0.74
Parietal Cortex Lesion	2 (10.5)	6 (12.5)	FET	1.00
Occipital Cortex Lesions	1 (5.3)	4 (8.3)	FET	1.00
Brain Surgery	3 (15.8)	1 (2.1)	FET	0.07

* FET = Fisher's Exact Test

Table 5

Comparison of those with and without aggression on duration of Loss of consciousness

	Aggression N=19 (N (%))	No Aggression N=47 (N (%))	X ²	df	P-value
LOC* < 30 minutes	10 (24.4%)	31 (75.6%)			
LOC > 30 minutes – 24hours	3 (33.3%)	6 (66.7%)			
LOC* >24 hours	6 (33.3%)	12 (66.7%)	.647	2	.72

* Loss of consciousness

Table 6

Comparisons of groups on clinical variables

Variables	Aggression	No Aggression	t	df	p=
Any Axis I Psychiatric Diagnosis Pre-TBI	15 (78.9)	36 (75.0)	FET		1.00
Major Depression Pre-TBI	2 (10.5%)	4 (8.3)	FET		1.00
Major Depression due to General medical condition (TBI)	5 (26.3)	2 (4.2)	FET		0.02
Major Depression Recurrent Post-TBI	0	1 (2.1)	FET		1.00
Post-TBI Anxiety Disorder	6 (31.6)	6 (12.5)	0.07	1	0.07
Pre-TBI Alcohol abuse/dependence	9 (47.4)	26 (54.2)	0.62	1	.79
Pre-TBI Substance abuse/dependence	9 (47.4)	24 (50)	0.85	1	1.00
Post Concussion Syndrome	6 (31.6)	5 (10.4%)	X ²	2	0.09
Childhood Behavior Problems	6 (31.6)	13 (27.1)	.71	1	0.77
Adult Behavior Pre-TBI	6 (31.6)	14 (29.2)	.85	1	1.00
Legal Problems Pre-TBI	8 (42.1%)	22 (45.8)	.78	1	1.00
Social Functioning Pre-TBI	.21 (.16)	.23 (.15)	.54	62	.59
Social Functioning Post-TBI	.33 (.15)	.25 (.14)	-2.2	64	.03
Social Ties Pre-TBI	.34 (.17)	.36 (.19)	.48	61	.63
Social Ties Post-TBI	.38 (.15)	.39 (.18)	.32	64	.75
Personal & Instrumental activities of daily living Pre-TBI	.5 (1.5)	1.1 (4.0)	.65	61	.52
Personal & Instrumental activities of daily living Post-TBI	9.6 (8.1)	5.3 (6.6)	-2.3	64	.03

Table 7

Comparisons of groups on neuropsychological tests

Variables	Aggression	No Aggression	t	df	p=
BTA	6.05 (2.9)	6.30 (3.4)	.280	63	.780
BVMT Total 3 trials	19.13 (7.8)	19.59 (7.4)	.203	57	.840
