Abstract

Antimicrobial peptides (AMPs) selectively disrupt bacterial cell membranes to kill bacteria whereas they either do not or weakly interact with mammalian cells. The orientations of AMPs in lipid bilayers mimicking bacterial and mammalian cell membranes are related to their antimicrobial activity and selectivity. In order to better understand the role of AMP-lipid interactions on the functional properties of AMPs, we determined the membrane orientation of an AMP (MSI-78 or pexiganan) in various model membranes using sum frequency generation (SFG) vibrational spectroscopy. Solid supported single 1,2-Dipalmitoyl-an-Glycero-3-[Phospho-rac-(1-glycerol)] (DPPG) bilayer or 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-[Phospho-rac-(1-glycerol)] (POPG) bilayer was used as model bacterial cell membrane. Supported 1,2-Dipalmitoyl-an-Glycero-3-Phosphocholine (DPPC) bilayer or 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-Phosphocholine (POPC) bilayer was used as model mammalian cell membrane. Our SFG results indicate that the helical MSI-78 molecules are associated with the bilayer surface with $\sim 70^\circ$ deviation from the bilayer normal in the negatively charged gel-phase DPPG bilayer at 400 nM peptide concentration. On the other hand, when the concentration was increased to 600 nM, MSI-78 molecules change orientation to make a 25° tilt from the lipid bilayer normal; whereas multiple orientations were observed for even higher peptide concentration in agreement with toroidal-type pore formation as reported from a previous solid-state NMR study. In contrary, no interaction between MSI-78 and a zwitterionic DPPC bilayer was observed even at a much higher peptide concentration (~ 12000 nM). These results demonstrate that SFG can provide insights into the antibacterial activity and selectivity of MSI-78. Interestingly, the peptide exhibits a concentration-dependent membrane orientation in lamellar phase POPG bilayer and also found to be inducing toroidal-type pore formation. The deduced lipid flip-flop from SFG signals observed from lipids also supports MSI-78 induced toroidal-type pore formation.

1. Introduction

Various peptides have been designed and tested as antimicrobial compounds to prevent bacterial drug resistance.^{1,2} It has been widely shown that antimicrobial peptides (AMPs) can differentiate mammalian cell membranes from bacteria cell membranes and selectively kill bacteria without harming mammalian cells.^{3–7} An ideal AMP should have high efficacy in killing bacterial cells and no hemolytic activity. Examination of detailed structural information of AMPs associated with various cell membranes can lead to further understanding of peptide-membrane interactions, aiding in the design and development of AMPs with improved properties. Bacterial cell membranes contain $\sim 25\%$ negatively charged lipids, while a mammalian cell membrane usually consists of zwitterionic lipids such as phosphatidylcholine (PC). The electrostatic attraction between the negatively

charged lipids (like 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-[Phospho-rac-(1-glycerol)] or POPG) and a positively charged AMP is believed to be responsible for the binding of AMPs to bacterial cell membranes, but not the mammalian ones. To avoid the complexity of the native cell membrane, substrate supported lipid bilayers have been commonly used as models for the cell membrane.^{8–13} In this study we used such model membranes to investigate AMP-membrane interactions.

Many AMPs kill bacteria by disrupting their cell membranes. Several modes of actions of AMPs have been proposed: barrel stave, toroidal pore, carpet-like, and others.^{5,7,14–17} In these different modes of action, AMPs adopt different orientations relative to the membrane surface. Therefore important information regarding the AMP mode of action can be deduced by determining the membrane orientation of an AMP.

Recently a nonlinear optical spectroscopic technique, sum frequency generation (SFG) vibrational spectroscopy, has been successfully applied to determine membrane orientation of peptides (including AMPs) and proteins.^{18–26} SFG provides vibrational spectra of surfaces and interfaces with a submonolayer surface specificity.^{27–46} It requires only a very small amount of samples, and can probe surfaces and interfaces in real-time. NMR techniques have been widely used to investigate molecular interactions between AMPs and model cell membranes, and excellent results have been obtained in such studies.^{47–54} Unlike NMR, which uses pre-mixed multilayer lipid-peptide mixtures, SFG can probe interactions between AMPs and a single supported lipid bilayer in situ in real time.

MSI-78 (also known as pexiganan) is a designed synthetic peptide, an analog of magainin 2 but with a much higher antimicrobial activity and selectivity.^{54,55} Previous research on MSI-78 reported that it adopts an α -helical structure in a membrane environment. The orientation of MSI-78 molecules in membranes studied by using various techniques including NMR^{54,56–58} revealed that the amphipathic helical peptide is oriented on the surface of the lipid bilayer. While these results are exciting and provided insights into the function of MSI-78, NMR studies typically require ~milligram quantity of the peptide. On the other hand, there is significant interest in understanding the peptide-membrane interactions at a lower peptide concentration and experimental data under such conditions are unavailable for MSI-78. For example, experimental measurement from lipid bilayer samples containing a peptide concentration at the minimum inhibitory concentration (MIC) level or lower will provide physiologically relevant results.

In this paper, we report SFG experimental results on MSI-78 embedded in model bacterial and mammalian cell membranes. We determined the membrane orientations of MSI-78 in various lipid bilayers. Our results further reveal that MSI-78 can strongly interact with model bacterial cell membranes and induce strong disruptions whereas it could not disrupt model mammalian cell membrane at similar peptide concentrations.

2. Materials and Methods

2.1. Materials

MSI-78 is a 22-residue synthetic α -helical peptide (amino acid sequence G-I-G-K-F-L-K-K-A-K-K-F-G-K-A-F-V-K-I-L-K-K-NH₂), and was synthesized and purified using the standard method.⁵⁴ Different lipids were purchased from Avanti Polar Lipids (Alabaster, AL), including 1,2-Dipalmitoyl-an-Glycero-3-[Phospho-rac-(1-glycerol)] (DPPG), 1,2-Dipalmitoyl-D62-sn-Glycero-3-[Phospho-rac-(1-glycerol)] (d-DPPG), 1,2-Dipalmitoyl-an-Glycero-3-Phosphocholine (DPPC), 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-[Phospho-rac-(1-glycerol)] (POPG) and 1-Palmitoyl-2-Oleoyl-sn-Glycero-3-Phosphocholine (POPC). The molecular structures of the lipids are shown in scheme 1. Right-angle CaF₂ prisms were

purchased from Altos (Trabuco Canyon, CA). The CaF_2 prisms were soaked in toluene for 1 day and then sonicated in Contrex AP solution from Decon Laboratories (King of Prussia, PA) for 1 hour. After that, they were cleaned in methanol for 10 minutes and then rinsed thoroughly with deionized water. The prisms were treated in a glow discharge plasma chamber for 4 minutes immediately before the deposition of lipids on them. The Langmuir-Blodgett and Langmuir-Schaefer (LB/LS) methods were used to deposit the proximal and the distal leaflets of a single lipid bilayer onto the prisms, respectively. A KSV2000 LB system and ultrapure water from Millipore system (Millipore, Bedford, MA) were used throughout the experiments for bilayer preparation, as described previously.¹⁸ In our experiments, we used the negatively charged DPPG/d-DPPG or POPG/POPG bilayers to represent bacterial cell membranes. The zwitterionic DPPC/DPPC or POPC/POPC bilayers were used to model mammalian cell membranes for comparison. The transition temperature between gel and fluid phase for POPG or POPC lipid is -2°C while for DPPG (d-DPPG) or DPPC lipid is 41°C . All of the experiments were carried out at room temperature ($\sim 24^\circ\text{C}$), at which the DPPG/d-DPPG and DPPC/DPPC bilayers are in the gel phase while the POPG/POPG and POPC/POPC bilayers are in the fluid phase. In peptide - lipid bilayer interaction experiments, an appropriate amount of MSI-78 aqueous stock solution was injected into a reservoir filled with 2 mL ultrapure water (in contact with the supported lipid bilayer) to achieve the desired peptide solution concentration. The SFG spectra were then collected after the peptide - lipid bilayer interaction reached equilibrium and SFG signal became stable (around 1 hour after the injection of the peptide solution to the subphase of the lipid bilayer). A magnetic micro stirrer was used to ensure a homogeneous concentration distribution of MSI-78 in the subphase below the lipid bilayer.

2.2. SFG

SFG is a second-order nonlinear optical spectroscopic technique that has submonolayer surface sensitivity. The details regarding SFG theories and measurements have been published previously,²⁷⁻⁴⁶ and will not be repeated here. The SFG setup used in this study was purchased from EKSPLA. In our experiments here, two laser beams (a 532 nm visible and a frequency tunable infrared) are overlapped in space and time on the sample, generating a signal at the sum frequency ($\omega_{\text{vis}} + \omega_{\text{ir}} = \omega_{\text{sum}}$). The pulse energies of both input beams are around 100 μJ , and the beam sizes are around 500 μm . By controlling the polarizations of the input and generated signal beams, information on interfacial molecular orientation can be obtained. All the spectra presented in this paper were collected using a near total internal reflection geometry⁵⁹ with ssp (s-polarized output SFG signal, s-polarized input visible beam, and p-polarized input IR beam) and ppp polarization combinations with 100 shots for each data point. For peptide amide I spectra, at least five same spectra were collected and averaged for data analysis.

The AMP conformation can be deduced from the peak center of the SFG amide I signal. For an α -helical structure, the amide I signal is centered at about 1650 cm^{-1} .⁶⁰ The orientation of an α -helical peptide can be determined by using SFG amide I spectra collected with ssp and ppp polarization combinations.^{18,61} This method has been applied to examine the membrane orientation of α -helical structures such as magainin 2,¹⁸ alamethicin,²³ melittin,²⁰ cytochrome b5,²⁶ and G-protein.²⁵

3. Results and Discussion

3.1 MSI-78 in a DPPG/d-DPPG lipid bilayer

After the MSI-78 stock solution was injected into the subphase of the DPPG/d-DPPG (DPPG as the proximal leaflet and d-DPPG as the distal leaflet) bilayer, SFG signal at 1650 cm^{-1} was monitored as a function of time. At a peptide concentration of 300 nM, no

discernible SFG signal was detected in the amide I frequency region. This can be explained by the fact that the interaction between MSI-78 molecules and DPPG/d-DPPG bilayer could be very weak at this low peptide concentration. For higher concentrations, SFG signal at 1650 cm^{-1} was detected and reached equilibrium at about one hour after the peptide injection into the subphase. SFG ppp and ssp spectra of MSI-78 in a DPPG/d-DPPG bilayer were then collected. Figure 1 shows the spectra collected after a 400 (top) or 600 nM (bottom) MSI-78 solution contacted the DPPG/d-DPPG bilayer (after one hour). In Figure 1, all amide I SFG spectra exhibit a dominant peak centered at 1650 cm^{-1} , indicating that MSI-78 adopts an α -helical structure associated with a DPPG/d-DPPG bilayer.⁶⁰ The solid lines in Figure 1 are the fitting results. Details of the SFG peak fitting methods have been described in previous publications¹⁸ and will not be reiterated here. According to the fitting results, we obtained the measured ppp and ssp signal strength ratio (or $\chi_{\text{ppp}}/\chi_{\text{ssp}}$) of 2.0 for 400 nM or 1.5 for 600 nM MSI-78 solution. By using this ratio, we can determine the orientation angle of MSI-78 in the DPPG/d-DPPG bilayer.

SFG orientation analysis for an α -helical structure has been described in our previous publications.^{18,61} We defined that the orientation angle θ represents the tilt angle between the principal axis of the α -helical MSI-78 molecule and the DPPG/d-DPPG bilayer surface normal. The relation between the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ ratio of MSI-78 and the α -helix orientation angle θ can be deduced using the developed method, assuming a δ -orientation distribution (Figure 2).⁶¹ Using Figure 2 and the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ ratios, we deduced that the orientation angle θ of MSI-78 associated with the DPPG/d-DPPG bilayer is around 70° (or 25°) when the bilayer contacting with 400 (or 600) nM MSI-78 solution. Other concentrations of MSI solutions were also tested in the experiment. As shown in Figure 2, when the MSI-78 solution concentration increased, the tilt angle θ decreases, meaning that the orientation of MSI-78 molecules changes from “surface orientation” towards “transmembrane” in the DPPG/d-DPPG bilayer. At 400 nM, MSI-78 molecules are 70° tilted from the bilayer normal. At the peptide concentration of 500 nM, the orientation angle changed from 70° to 65° . When the peptide concentration was increased to 600 nM, the orientation angle changed to 25° , near to the transmembrane orientation. This shows that the increase in the peptide concentration enables the MSI-78 molecules to change their orientations from perpendicular to the DPPG/d-DPPG bilayer normal to the parallel orientation. As the concentration continued to increase to 800 nM, the orientation angle of MSI-78 molecules was determined to be approximately 15° vs. the bilayer normal. At an even higher concentration of 2000 nM, the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ ratio equals to 1.3, which is below the possible values in the calculated curve assuming a δ -orientation distribution (Figure 2). Under the assumption that every MSI molecule adopts the same orientation (or a δ -orientation distribution), the value of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ should be between 1.40 and 2.05. The observation for a low peptide concentration is in excellent agreement with previous solid-state NMR studies⁵⁴ whereas the change in the tilt angle at higher concentrations (500 to 800 nM) indicates that the peptide could be aggregating to insert into the hydrophobic region of the bilayer. Such “transmembrane” orientations were not observed from NMR experiments⁵⁸ and therefore we believe that there are two different mechanisms operative for low ($<\mu\text{M}$) and high concentration of the peptide.

Previously, when we used SFG to investigate the orientation of melittin molecules in a DPPG/DPPG bilayer,²⁰ we observed the same phenomenon and found that the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ value was below the possible values of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ assuming a δ -orientation distribution for melittin. The combined SFG and ATR-FTIR study showed that melittin molecules associated with the lipid bilayer adopt two distinct orientations: about a quarter of the melittin molecules orient almost perpendicularly inside the lipid bilayer while the rest orient almost parallel to the bilayer surface.²⁰ Here we believe that for MSI-78, when the peptide concentration reaches 2000 nM, the MSI-78 molecules also adopt multiple

orientations. This interpretation is similar to the solid-state NMR observations that MSI-78 functions via toroidal-pore formation, where the peptide exists in multiple orientations.⁵⁴ This observation is also consistent with the membrane thinning effect observed from AFM experiments.⁵⁶ In addition, it is also possible that some of the lipids may be removed by the peptide (like a detergent) as revealed by the observation of isotropic chemical shift peaks in some samples for solid-state NMR.⁵⁸ Then some peptides may tilt or lie down on the bare CaF₂ substrate surface.

It has been shown in the previous studies that the MIC of MSI-78 against *E. coli* is around 5 μ M.^{55,62,63} In our experiment, the membrane insertion observed for concentrations <1 μ M may not result in bilayer disruption. But the multiple orientations observed at a higher concentration (2 μ M) could result in bilayer disruption via toroidal-type pore formation. Though the MIC is still higher than 2 μ M, it is reasonable because the *E. coli* cell membrane contains only about 32% anionic lipids, thus requiring a higher peptide concentration to effectively disrupt the cell membrane as revealed by the MIC value.

MSI-78 is a magainin 2 analog, but has different antimicrobial activity and selectivity.^{55,62,63} In our previous research, we investigated the molecular interactions between magainin 2 and different model cell membranes such as POPG/POPG and POPC/POPC bilayers.¹⁸ Similar results were observed from magainin 2 compared to MSI-78. At a low concentration of 200 nM, no SFG signal can be observed, indicating that magainin 2 molecules either do not interact with the bilayer or lie down on the bilayer surface.¹⁸ After increasing the magainin 2 concentration to 800 nM, the magainin 2 molecules insert into the POPG lipid bilayer and adopt a transmembrane orientation with an orientation angle of 20° from the bilayer normal.¹⁸

Different modes of AMP's action on lipid bilayers will result in different lipid bilayer changes and time-dependent changes, which in turn will correspond to different SFG spectral features and spectral changes as a function of time. In our experiment, we used isotopically asymmetric DPPG/d-DPPG (DPPG as the proximal leaflet and d-DPPG as the distal leaflet) bilayer. So, we could specifically monitor the proximal and the distal leaflets separately if we assume that no flip-flop occurred. The behavior of each leaflet of the bilayer was monitored by examining SFG spectra collected in the C-H stretching frequency regime (2750–3100 cm⁻¹) and C-D stretching frequency regime (2000–2300 cm⁻¹). Figure 3 shows the SFG spectra (ssp) in the (top) C-H and (bottom) C-D stretching frequency ranges collected from a DPPG/d-DPPG bilayer before and after contacting with MSI-78 solutions with different concentrations. MSI-78 contains some C-H groups, but their signals are much weaker than those from the DPPG leaflet. Therefore it is believed that the SFG C-H stretching signal is attributed to the proximal leaflet (DPPG) while SFG C-D stretching signal comes from the distal leaflet (d-DPPG).

As displayed in Figure 3, the overall SFG spectral intensity in the C-D stretching region dramatically dropped at the peptide concentration of 400 nM, while the SFG intensity in the C-H stretching region only changed slightly. As we showed above from SFG studies on the peptide amide I signals, MSI-78 tilts at about 70° in the bilayer. Therefore MSI-78 may only interact with the distal leaflet, and disrupt some order of the distal leaflet peptide chain. The C-D signals are dominated by the contributions from the end CD₃ groups of the distal leaflet. The orientations of such CD₃ groups must change substantially even when the peptide solution concentration is 400 nM when MSI-78 only interacts with the distal leaflet. Since the peptide does not interact with the proximal leaflet significantly, no large change of the CH signals was observed.

At the peptide concentration of 600 nM, both SFG C-D and C-H signal intensities decreased substantially, indicating that both the distal and proximal leaflets in the DPPG/d-DPPG bilayer were disrupted at this peptide concentration. According to the above SFG amide I signals, at this concentration, MSI-78 adopts a transmembrane orientation, which apparently can disrupt both leaflets. As the 400 nM study above, here SFG studies on the C-H and C-D stretching frequencies are well correlated to the SFG amide I signals reported above. At a high peptide concentration of 2000 nM, the SFG C-D and C-H stretching signals are very weak, showing that the lipid bilayer must be severely disrupted. At this situation MSI-78 molecules form toroidal-pores inducing flip-flop of lipids and there could be some removal of lipids via detergent-type interaction of the peptide with the bilayer.

We also followed the kinetics during the process when MSI-78 molecules interact with the DPPG/d-DPPG bilayers at different peptide concentrations. Such kinetics can be monitored by detecting SFG C-H and C-D stretching signal intensity change as a function of time. Time dependent SFG signals were monitored at 2875 cm^{-1} for CH_3 symmetric stretching mode from the proximal leaflet (DPPG) and at 2070 cm^{-1} for CD_3 symmetric stretching mode from the distal leaflet (d-DPPG). Signal decrease at 2875 cm^{-1} or 2070 cm^{-1} would indicate the perturbation (or disruption) in the proximal (DPPG) or the distal (d-DPPG) leaflet, respectively, or the reductions of the asymmetry of lipid bilayer induced by peptide insertion. Figure 4 shows such time-dependent signal changes at three different peptide solution concentrations while the MSI-78 stock solutions with different concentrations were injected at 200 s into the lipid subphase.

Figure 4 shows that after the 400 nM peptide solution was introduced, both SFG C-D and C-H stretching intensities started to decrease, but at very different extents. The C-D stretching signal, which was contributed from the distal leaflet (d-DPPG), was reduced much faster than the C-H stretching signal (from the proximal leaflet, DPPG). This result is again correlated well with the above observation. Because MSI-78 molecules only slightly tilt on the bilayer surface, they disrupted the distal leaflet first and significantly, but not substantially with the proximate leaflet. The SFG signal from the proximal leaflet only changed slightly, because MSI-78 molecules do not interact with the proximal leaflet much. When the peptide concentration increases to 600 nM, in addition to the substantial SFG C-D stretching signal intensity decrease, the SFG C-H stretching signal also decreased greatly, indicating that both the distal (d-DPPG) and proximal (DPPG) leaflets were disrupted at this concentration. This agrees with the observation that the MSI-78 molecules adopt a transmembrane orientation in the DPPG/d-DPPG bilayer. At an even high concentration of 2000 nM, both C-D and C-H stretching signals decreased quickly, showing that both the distal and the proximal leaflets were disrupted rapidly at this high concentration, along with the possible flip-flop. The time-dependent studies here further confirm the different interactions between MSI-78 and the DPPG bilayer at different peptide concentrations.

3.2. MSI-78 in a DPPC/DPPC lipid bilayer

After we studied interactions between MSI-78 and DPPG bilayers (models for bacterial cell membranes), we continued to study interactions between MSI-78 and DPPC bilayers (models for mammalian cell membranes). SFG ppp and ssp spectra of MSI-78 associated with DPPC/DPPC bilayers are shown in Figure 5. The spectra were collected after 6000 (top) or 12000 nM (bottom) MSI-78 solutions contacted with the DPPC/DPPC bilayer. As shown in Figure 5, there was no discernible SFG signal detected in the amide I frequency region at peptide concentrations of 6000 and 12000 nM. This can be explained by the fact that the MSI-78 molecules do not interact and are not associated with the DPPC/DPPC bilayer. The concentration we used here (12000 nM) is 30 times larger than that in the DPPG/d-DPPG bilayer study (400 nM), but still no MSI-78 molecules interact with the DPPC/DPPC bilayer. It is thus obvious that the interaction between MSI-78 and the DPPC/DPPC bilayer

is very weak, which is quite different from the interaction between MSI-78 and the negatively charged DPPG/d-DPPG bilayer. Because DPPC is a zwitterionic lipid, the positively charged MSI-78 cannot be attracted to the DPPC/DPPC bilayer because of the lack of electrostatic interaction. We can conclude that there is no observed interaction between MSI-78 and the model mammalian cell membrane. This can explain the excellent selectivity of MSI-78.

3.3. MSI-78 in a POPG/POPG lipid bilayer

POPG/POPG and POPC/POPC bilayers were used as models for bacterial and mammalian cell membranes in our previous SFG studies on magainin 2.¹⁸ Here, we also used anionic POPG/POPG bilayer to represent the bacterial cell membrane. We studied the interactions between MSI-78 and the POPG/POPG bilayer based on two reasons: Firstly, different from the gel phase DPPG/d-DPPG bilayer, the POPG/POPG bilayer is in the fluid phase at room temperature. The real cell membrane is in the fluid phase, therefore the fluid phase POPG/POPG should better represent the bacterial cell membrane compared to the DPPG/DPPG bilayer. Secondly, as shown in our previous paper, some peptides like alamethicin interact with gel and fluid phase lipid bilayers differently.²³ It was shown that alamethicin molecules lie down or aggregate on the gel phase lipid bilayer surface but can insert into the fluid phase lipid bilayer.²³ Therefore the use of lipids with different phases in the study should provide a more completed picture on MSI-78/cell membrane interactions.

SFG ppp and ssp spectra of MSI-78 in a POPG/POPG bilayer were collected as described above (Figure 6). The spectra were collected after the POPG/POPG bilayer contacted MSI-78 solutions with concentrations of 500 (top) or 800 nM (middle). At a lower peptide concentration of 400 nM, no discernible SFG signal in the amide I region could be detected from the POPG/POPG bilayer/peptide solution interface (data not shown). This can be explained by the fact that the interaction between MSI-78 and the POPG/POPG bilayer was very weak at such a low peptide concentration. At the concentration of 500 nM, both SFG ssp and ppp spectra exhibit a dominant peak centered around $\sim 1650\text{ cm}^{-1}$, which confirms that MSI-78 adopted an α -helical structure in the fluid phase POPG/POPG bilayer (similar to that in the gel phase DPPG bilayer above).⁶⁰ The weak signal at about 1730 cm^{-1} in the ppp spectrum for 500 nM is from the lipid bilayer, not the peptide.

The fitted experimentally signal strength ratio of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ for the $\sim 1650\text{ cm}^{-1}$ peak equals to 1.39 and 1.19 for 500 and 800 nM MSI-78 solutions, respectively. Figure 6 (bottom) displays the relationship between the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ ratio and the orientation angle θ for MSI-78 molecules. At the concentration of 500 nM, the tilt angle between the principal axis of MSI-78 molecules and the POPG/POPG bilayer surface normal is around 0° , indicating that MSI-78 molecules insert into the POPG/POPG bilayer and adopt a transmembrane orientation at this concentration. When the MSI-78 solution concentration is increased to 600 or 800 nM, the measured ratio of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ is below the calculated curve (assuming a δ -orientation distribution) in Figure 6, showing that MSI-78 molecules may have more than one distinct orientations – at these conditions the toroidal pores are formed as discussed earlier. Also the lipid bilayer might be severely disrupted as discussed above. At the concentration of 500 nM, it is sufficient for MSI-78 molecules effectively interact with the lamellar-phase POPG/POPG bilayer, so these peptides adopt a transmembrane orientation. Our previous gel-phase DPPG/d-DPPG bilayer results indicate that such a concentration for the DPPG bilayer is around 600 nM, which is similar to the fluid phase POPG/POPG bilayer result (500 nM).

The orientation angle at 0° may not be the only possible solution for 500 nM. Possibly at this concentration peptides already started to adopt multiple orientations, which may also

satisfy the experimentally signal strength ratio of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ of 1.39. To further quantify the orientation, we will include more measurements in the experiment.²⁰

3.4. MSI-78 in a POPC/POPC lipid bilayer

Lastly, we used the fluid phase POPC/POPC bilayer as a representation of the model mammalian cell membrane. Different from negatively charged POPG lipid, POPC is a zwitterionic lipid. The SFG ppp and ssp spectra of MSI-78 molecules in a POPC/POPC bilayer are shown in Figure 7. The spectra were collected after 1000 (top) or 2000 nM (middle) MSI-78 solution contacted with the POPC/POPC bilayer. Different from the POPG result, at the concentration of 800 nM, no discernible SFG signal in the amide I region could be detected (data not shown), which shows that either the MSI-78 molecules do not bind to the POPC/POPC bilayer, or the MSI-78 coverage on POPC/POPC bilayer is not high enough, or the MSI-78 molecules completely lie down on the bilayer surface. Increasing the MSI-78 concentration to 1000 nM, a very weak SFG signal (around 7 in the SFG ppp spectra) in the amide I frequency region was observed, showing that perhaps a small amount of peptides were associated to the POPC/POPC bilayer at this concentration. This observation is different from the gel phase DPPC/DPPC bilayer result. For the DPPC bilayer, as we showed in Figure 5, no detectable SFG signal was observed even at a much higher MSI-78 concentration of 12000 nM, indicating that there is no interaction between MSI-78 and the DPPC/DPPC bilayer. Here we believe that the weak SFG signal from the MSI-78 in fluid phase POPC/POPC bilayer may be due to a small amount of MSI-78 peptides associated with the bilayer. The fitted experimentally signal strength ratios of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ at the peak center of $\sim 1650 \text{ cm}^{-1}$ are 1.13 and 1.08 for 1000 and 2000 nM peptide solutions, respectively. Figure 7 (bottom) again shows the relationship between the measured $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ ratio and the orientation angle θ for MSI-78 molecules. At the concentration of 1000 or 2000 nM, the measured ratio of $\chi_{\text{ppp}}/\chi_{\text{ssp}}$ is below the calculated curve assuming a δ orientation distribution in Figure 7. MSI-78 molecules thus again have more than one distinct orientation suggesting that the lipid bound peptides induce toroidal-type pore formation.

Although we observed the SFG amide I signals from MSI-78 in both POPG/POPG and POPC/POPC bilayers, the interactions between MSI-78 molecules and the two lipid bilayers are very different: (1) The SFG intensities of MSI-78 with the two lipid bilayers are very different. SFG intensity detected from MSI-78 associated with the POPG/POPG bilayer is about 16 (intensity counts) at the peptide concentration of 500 nM; the SFG intensity of MSI-78 in the POPC/POPC bilayer is much weaker, which is only about 7 (intensity counts) at a much high peptide concentration of 1000 nM. Even we double this concentration to 2000 nM, the SFG intensity from MSI-78 in the POPC/POPC bilayer is still much weaker than that in the POPG/POPG bilayer at the low peptide concentration of 500 nM. (2) The orientation angle of MSI-78 molecules should be very different in these two kinds of lipid bilayers. For the POPG/POPG bilayer, the MSI-78 molecules insert into the membrane bilayer at a peptide concentration of 500 nM with the measured orientation angle of 0° versus surface normal. After increasing the peptide concentration to 600 or 800 nM, toroidal pores may be formed, generating multiple peptide orientations. Also, the lipid bilayer may be severely disrupted or demolished and the peptide molecules could adopt a dual δ -function orientations. On the other hand, the MSI-78 molecules with one distinct orientation in POPC/POPC bilayer were never observed at any peptide concentrations because of the lack of electrostatic attraction between MSI-78 and the zwitterionic lipid bilayer. This could be because the hydrophobic interaction dominates above certain peptide concentration enabling multiple orientations directly via toroidal-type pore disruption. Thus, the observed differences on the interactions between MSI-78 and the anionic POPG/POPG versus

zwitterionic POPC/POPC bilayers show a clear evidence that MSI-78 interact with bacterial cell membrane and mammalian cell membrane quite differently.

4. Conclusion

In this paper, the orientation angles of MSI-78 molecules in different model membrane environments have been measured using SFG amide I spectra detected with different polarization combinations. The SFG orientation analysis on α -helical structures used here is based on a methodology developed previously in our lab. We compared the orientations of MSI-78 molecules in both model bacterial (DPPG or POPG) and mammalian (DPPC or POPC) cell membranes. For a gel phase DPPG/d-DPPG bilayer, at a low peptide concentration of 400 nM, MSI-78 molecules oriented on the surface of lipid bilayer as reported from solid-state NMR studies;⁵⁴ when the peptide concentration is increased to 600 nM, MSI-78 molecules insert into the lipid bilayer. Heterogeneous membrane orientations observed at a higher peptide concentration is also in complete agreement with solid-state NMR studies⁵⁸ that revealed the formation of toroidal pores due to MSI-78 interaction with lipid bilayers. In contrary, there is no interaction between MSI-78 and the zwitterionic gel-phase DPPC/DPPC bilayer even at a much higher peptide concentration of 12000 nM. For fluid lamellar-phase POPG/POPG bilayer, the lipid bilayer could be disrupted at the peptide concentration of 500 nM, while the MSI-78 molecules insert into lipid bilayer and eventually disrupting the bilayer via toroidal pores. While for the POPC/POPC bilayer, there is no interaction between MSI-78 and the lipid bilayer below the peptide concentration of 1000 nM. These results demonstrate that MSI-78 molecules can easily interact with (or disrupt) the bacterial model cell membranes (DPPG or POPG bilayer), but disruption of the mammalian model cell membranes (DPPC or POPC bilayer) is much more difficult. Finally, we believe that SFG measurements at a very low peptide concentration (nearly close to or below the MIC value) can provide fundamental insights into the function of an antimicrobial peptide.
