Abstract

Homoprotocatechuate (HPCA; 3,4-dihydroxyphenylacetate or 4-carboxymethyl catechol) and O₂ bind in adjacent ligand sites of the active site Fe^{II} of Homoprotocatechuate 2,3-Dioxygenase (FeHPCD). We have proposed that electron transfer from the chelated aromatic substrate through the Fe^{II} to O₂ gives both substrates radical character. This would promote reaction between the substrates to form an alkylperoxo intermediate as the first step in aromatic ring cleavage. Several active site amino acids are thought to promote these reactions through acid/base chemistry, hydrogen bonding, and electrostatic interactions. Here the role of Tyr257 is explored by using the Tyr257Phe (Y257F) variant, which decreases k_{cat} by about 75%. The crystal structure of the FeHPCD-HPCA complex has shown that Tyr257 hydrogen bonds to the deprotonated C2-hydroxyl of HPCA. Stopped-flow studies show that at least two reaction intermediates, termed Y257F^{HPCA}_{Int1} and Y257F^{HPCA}_{Int2}, accumulate during the Y257F-HPCA + O₂ reaction prior to formation of the ring-cleaved product. Y257F^{HPCA}_{Int1} is colorless and is formed as O₂ binds reversibly to the HPCA-enzyme complex. Y257F^{HPCA}_{Int2} forms spontaneously from Y257F^{HPCA}_{Int1} and displays a chromophore at 425 nm ($\epsilon_{425} = 10,500 \text{ M}^{-1} \text{ cm}^{-1}$). Mössbauer spectra of the intermediates trapped by rapid freeze quench show that both intermediates contain Fe^{II}. The lack of a chromophore characteristic of a quinone or semiquinone form of HPCA, the presence of Fe^{II}, and the low O₂ affinity suggests that Y257F^{HPCA}_{Int1} is an HPCA-Fe^{II}-O₂ complex with little electron delocalization onto the O₂. In contrast, the intense spectrum of Y257F^{HPCA}_{Int2} suggests the intermediate is most likely an HPCA quinone-Fe^{II}-(hydro)peroxo species. Steady-state and transient kinetic analyses show that steps of the catalytic cycle are slowed by as much as 100-fold by the mutation. These effects can be rationalized by a failure of Y257F to facilitate the observed distortion of the bound HPCA that is proposed to promote transfer of one electron to O₂.

Homoprotocatechuate 2,3-dioxygenase (FeHPCD) from *Brevibacterium fuscum* catalyzes the insertion of both atoms from O₂ into the aromatic ring of homoprotocatechuate (HPCA, 3,4-dihydroxybenzoate) resulting in ring opening as shown in Scheme 1.^{1,2}

SUPPORTING INFORMATION AVAILABLE

Supporting results, Figures S1–S3. This material is available free of charge via the internet at <http://pubs.acs.org>.

The enzyme utilizes an Fe^{II} , which is bound in the active site by two histidine and one glutamic acid side chains in a 2-His-1-carboxylate facial triad motif shown in Figure 1A.³⁻⁷ Substrates bind in multistep processes to displace solvents from the Fe^{II} and form a chelate complex.⁸ For catecholic substrates such as HPCA with relative high pK_a values for the hydroxyl substituents, only the C2-hydroxyl group deprotonates upon binding, so that the overall charge of the metal center is neutral.^{3-5,9} Crystallographic studies have shown that small molecules such as O_2 and the O_2 surrogate NO bind in the open ligand site of the Fe^{II} adjacent to the substrate.^{5,6} We and others have proposed the mechanism summarized in Scheme 1 in which an electron is transferred from the aromatic substrate through the iron to the oxygen, giving both substrates radical character ($\text{SQ}^{\bullet}\text{-Fe}^{\text{II}}\text{-O}_2^{\bullet-}$).^{8,10-14} Recombination of the radicals would yield an alkylperoxo intermediate. A subsequent Criegee-type rearrangement would result in O-O bond cleavage to yield a substrate lactone intermediate with the second atom of oxygen retained on the iron. Hydrolysis of the lactone by this oxygen would yield the bound product ready for release.

Crystallographic studies in which the slow alternative substrate 4-nitrocatechol (4NC) was diffused anaerobically into the crystal and the reaction initiated by exposure to low concentrations of O_2 , have allowed the $\text{SQ}^{\bullet}\text{-Fe}^{\text{II}}\text{-O}_2^{\bullet-}$ (Figure 1B), alkylperoxo, and the product complexes to be structurally characterized.⁶ A gem-diol intermediate (or stabilized form), which presumably occurs between the alkylperoxo and lactone intermediates, was trapped in a crystal and structurally characterized using a similar approach.¹⁵ These studies and earlier structural studies of the FeHPCD-HPCA complex³ have revealed several residues in the active site that are likely to facilitate catalysis (Figure 1A). In particular, residue His200 is positioned to interact with both the substrate C4-OH substituent and the bound oxygen. Mutation of this residue indicates that it plays many roles including that of an acid-base catalyst to promote the Criegee rearrangement chemistry.¹² It may also serve to sterically promote the side-on binding orientation of the oxygen in the $\text{SQ}^{\bullet}\text{-Fe}^{\text{II}}\text{-O}_2^{\bullet-}$ complex revealed by the crystal structure and to stabilize the oxy complex by a combination of hydrogen bonding and charge interaction with the bound superoxo anion (Figure 1B). Substitution of His200 by shorter residues that cannot effectively hydrogen bond or catalyze acid-base chemistry and/or the use of alternative substrates greatly slow catalysis, allowing several intermediates to be trapped by rapid freeze quench (RFQ) techniques for spectroscopic characterization.^{16,17}

Another active site residue, Tyr257, also appears to be important for catalysis based on its interaction with the HPCA C2- O^- . This residue is located on the opposite side of the substrate from His200 and forms a hydrogen bond with the deprotonated substrate hydroxyl (Figure 1A). We postulate that Tyr257 promotes oxygen activation, ring attack, and ring cleaving chemistry in several ways related to favoring a tetrahedral geometry at the carbon bearing this hydroxyl. This proposal is based on the observation that the structurally characterized intermediates exhibit an increasingly tetrahedral substrate C2 as they progress toward product formation (see for example Figure 1B).^{6,15} Consequently, active site structural elements that favor sp^3 hybridization at substrate C2 should promote each step of the reaction.

Here we explore the roles of Tyr257 in catalysis by mutating it to a Phe (Y257F), which preserves the spatial characteristics of Tyr, but not the ability to hydrogen bond or sterically interact with the substrate via the Tyr hydroxyl substituent. It is found that, in accord with the postulated role for Tyr257, the Y257F-HPCA + O_2 reaction forms a ring-cleaved product with kinetics that are slow in comparison to those of the wild-type reaction. The slow internal steps of the Y257F reaction cycle allow new intermediates to be detected, trapped, and characterized. The new intermediates support the proposed requirement for electron transfer to the oxygen from the substrate without a net change in metal oxidation

state prior to O₂ attack in order to sustain efficient catalysis. The structural bases for the roles of Tyr257 are explored in the accompanying report.²

EXPERIMENTAL PROCEDURES

Reagents and Enzymes

All chemicals were purchased from Sigma-Aldrich and were used without purification except for HPCA which was recrystallized from water at 4 °C to remove minor contaminants. Anaerobic conditions were achieved by repeated cycling of solutions between argon gas and vacuum. Trace contaminating O₂ was removed from the Ar gas by passage through an Agilent GC-1 POP O₂ scrubbing cartridge, then through an Agilent GC-4 POP O₂ indicating cartridge. Mushroom tyrosinase was purchased from Sigma-Aldrich.

Y257F Variant

Y257F mutant of FeHPCD was prepared using the Stratagene QuickChange kit. The following mutagenesis primer was used along with its reverse complement:

GGCTCTCCAACGCGTTCTACCTG**TTC**ATCC.

The mutant codon is shown in bold highlight. The mutation was confirmed via sequencing at the University of Minnesota MicroChemical Facility.

Recombinant WT FeHPCD and Y257F were purified as previously described^{1,12} with a few modifications. No cysteine or Fe was added to the purification buffers, but all buffers used in the purification were continually sparged with 1 psi of N₂ to remove O₂. After loading FeHPCD onto the DEAE Sepharose column, the column was gravity washed with 10 column volumes of buffer (50 mM MOPS pH 6.8 + 190 mM NaCl). The wash buffer is sparged with 1 psi of N₂ during this process. After the wash, a salt gradient totaling 10 column volumes was run from 190 – 350 mM NaCl using a gravity dependent gradient maker sparged with 1 psi N₂ in the mixing chamber (chamber with low salt buffer). The pooled fractions from the DEAE Sepharose column were found to be sufficiently pure for kinetic and spectroscopic studies. Purified Y257F yielded the correct ring cleaved product from HPCA.

The isotope ⁵⁷Fe was incorporated into the enzyme by growth on ⁵⁷Fe enriched media as previously described except that the media contained 4 g/L yeast extract and 4 ml/L of filter sterilized glycerol.¹⁶ Mössbauer analysis of the purified Y257F mutant revealed ~1 eq of ⁵⁷Fe^{II}/site enrichment as previously described for the wild type enzyme and the H200N mutant.^{16,17}

Iron Quantification using ICP-OES

The ICP-OES samples are digested in 20% nitric acid at 37 °C for at least 24 h. Insoluble materials were removed by centrifugation at 10,000 × g at 4 °C. The supernatant was analyzed for transition metals using ICP-OES at the Aqueous Geochemistry Lab (University of Minnesota, Department of Earth Science).

Stopped-Flow Kinetics and Spectroscopy

All stopped-flow experiments were performed using an Applied Photophysics model SX. 18MV stopped-flow device. The reaction procedures were as previously described.⁸ All stopped-flow experiments were conducted at 4 °C in 50 mM MOPS buffer at pH 7.5 or 50 mM MES buffer at pH 5.5, as previously described.¹⁷ Solutions varying in O₂ concentrations were prepared by diluting a stock saturated O₂ buffer solution with anaerobic buffer in a gas-tight 5 ml Hamilton syringe equilibrated on ice. The kinetic data were

analyzed to extract reciprocal relaxation times using the Applied Photophysics Pro-Data Viewer version 4.0.17. In general, the reaction time courses were fit to summed exponential expressions, which are appropriate for series of first order or pseudo first order reactions.¹⁸ EPR spectra were collected using a Bruker Elexsys E-500 spectrometer equipped with a Bruker dual mode cavity and an Oxford ESR 910 liquid helium cryostat. Mössbauer spectroscopy was performed as previously described.^{16,19} Spectra were analyzed using the software WMOSS (SEE Co, Edina, MN, USA).

Steady-State Kinetic Experiments

Steady-state kinetic parameters for the ring-cleaving reaction of FeHPCD and the Y257F variant were monitored using UV-vis detection. The initial velocity of product formation was observed at 380 nm using a stopped-flow device. The linear portion of the trace was fit using the Pro Data Viewer software package. The enzyme concentration was 1 μ M for FeHPCD and 3 – 6 μ M for Y257F after mixing with varying HPCA substrate concentrations. Experiments were done at either 4 °C or 22 °C in 200 mM MES or MOPS buffer at pH 5.5 or pH 7.5, respectively, in air saturated buffer as noted in the figure legends. Initial velocities were fit as a hyperbolic function of substrate concentration to determine K_m and V_{max} using the data analysis software in Origin.

Rapid Freeze Quench (RFQ) Methods

Y257F-HPCA anaerobic complex (1.6 mM) was prepared in the glove box by mixing 1 eq of Y257F with 1 eq of HPCA. RFQ syringes were loaded inside the Coy anaerobic glove box and then transferred to an Update Instrument model 1019 RFQ apparatus and allowed to equilibrate for 30 min at 4 °C. The RFQ samples were mixed with O₂ buffer as previously described.¹⁷ Previously, we observed a splash artifact when the shortest time reaction mixtures were frozen on the counter-rotating aluminum wheels maintained at Liq N₂ temperature.¹⁷ To avoid this artifact, the instrument was redesigned to rotate the wheels at a higher velocity and plastic scrapers were placed to remove the frozen solution from the wheels each cycle. This allowed the reaction mixture to always contact the metal surface rather than frozen solution on the wheel. Samples at times > 1 s were frozen as previously described.¹⁷

Preparation of HPCA Semiquinone and HPCA Quinone

HPCA was oxidized to a quinone using mushroom tyrosinase (Sigma) in 100 mM MOPS buffer pH 7.5 and 4 °C. A solution of 2 mM HPCA was mixed with 10 mg/ml mushroom tyrosinase. The quinone formed during the first 4 min of the reaction. It is photo-labile and decays to an unidentified secondary species over the next 10 min. HPCA was oxidized to a transient semiquinone by oxidation with 3,4,5,6-tetrachloro-1,2-benzoquinone (O-chloranil, Sigma-Aldrich) in ethanol at 20 °C.^{20,21} The reaction was initiated and monitored using the stopped-flow spectrometer with diode-array detection (2 mm path). A solution of 2 mM HPCA was mixed with 2 mM of O-chloranil. The semiquinone formed during the first 150 s of the reaction and then slowly decayed to an unidentified species.

RESULTS

The Y257F Variant of FeHPCD Reacts Slowly

The steady-state parameters for Y257F with the HPCA substrate were determined at 4 and 22 °C and at pH 7.5 and pH 5.5 by monitoring the initial velocity of product formation using stopped-flow spectroscopy as summarized in Table 1. An example of the Michaelis-Menten plot for HPCA varied at pH 7.5 and 4 °C is shown in Figure S1. The results show that the

k_{cat} value decreases to about 27% of that of the WT enzyme at pH 7.5, 22 °C. The $K_{\text{m}}^{\text{HPCA}}$ is increased by about 16 fold by the mutation, whereas $K_{\text{m}}^{\text{O}_2}$ is increased only slightly.

Substrate Binds Tightly to Y257F

Direct determination of the K_{d} for HPCA is complicated by the lack of a visible or fluorescence change upon binding. However, the K_{d} can be approximated by comparison to 4NC binding. The K_{d} for 4NC for WT enzyme has been previously determined to be 5 μM based on the spectroscopic change that occurs as monoanionic 4NC in solution converts to the dianionic form bound to the enzyme.⁸ The fraction of 4NC bound upon addition of a fixed concentration to Y257F is the same as that observed for the WT enzyme, showing that the K_{d} does not change significantly (Figure 2, blue and black traces). When HPCA and 4NC are added in equal concentrations to either FeHPCD or Y257F, only the spectrum of free 4NC is observed, showing that HPCA binds much tighter than 4NC ($K_{\text{d}} > 5 \mu\text{M}$) in each case (Figure 2, red trace). This is not the case when a weak binding substrate 4-chlorocatechol (4CC) is added instead of HPCA (Figure 2, green and black traces). These results suggest that the relatively high $K_{\text{m}}^{\text{HPCA}}$ value observed for Y257F must be attributed to reaction cycle steps other than those associated with formation of the final substrate complex. The low K_{d} value facilitates transient kinetic experiments as described below.

Single-Turnover Studies of the Y257F-HPCA + O₂ Reaction Reveal Two Reaction Intermediates

The diode-array stopped-flow spectra from an experiment wherein anaerobic, stoichiometric Y257F-HPCA complex reacts with a large excess O₂ at 4 °C at pH 7.5 or pH 5.5 are shown in Figures 3A and B, respectively. There is little change in the spectra in the first 30 ms at either pH value. Indeed, single wavelength data at 450 nm from pH 7.5 and pH 5.5 diode-array time courses clearly reveal a lag-phase during this period (Figure 3A and B insets). This suggests that there is at least one colorless intermediate formed at the outset of the reaction before formation of a chromophoric species.

At slightly longer times, a transient species with a chromophore in the 400 – 470 nm range is observed. At pH 7.5, the chromophore begins to appear after 30 ms and maximizes at ~ 250 ms before it decays over the course of several seconds to yield the extradiol ring-cleaved product ($\lambda_{\text{max}} = 380 \text{ nm}$). The spectrum of the transient species has an isosbestic point with that of the ring-cleaved product, so it may be the direct precursor of product formation in the reaction cycle. However, it is possible that other short-lived intermediates may intervene.

It was previously shown that λ_{max} for the ring-cleaved product shifts to shorter wavelength at low pH.¹⁷ Accordingly, when the Y257F-HPCA + O₂ reaction is conducted at pH 5.5, λ_{max} for the ring-cleaved product shifts to 325 nm, revealing the chromophore associated with the new intermediate at 425 nm (Figure 3B). The pH 5.5 data shows that the new intermediate maximizes at ~ 700 ms, suggesting one or both rate constants for formation and decay of this species have changed at low pH. We will term the first and second new intermediates $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$, respectively.

Rate Constants for the Formation and Decay of the Intermediates

Single-wavelength kinetic time courses were analyzed using regression methods to obtain reciprocal relaxation times ($1/\tau$ values) associated with the reaction. Figure 4 shows the single wavelength time course monitored under pseudo first order conditions at 450 nm or 350 nm for the first 15 s of the Y257F-HPCA + O₂ reaction at pH 7.5 or 5.5, 4 °C. Each of the time courses requires four summed exponential phases to achieve a satisfactory fit

(summarized in Table 2). The slowest phase is not kinetically competent and arises from a photochemical side reaction of the product bound to the enzyme as described in Supporting Information (Figure S2).

Observation of at least three competent phases in product formation at pH 5.5 and pH 7.5 shows that the Y257F-HPCA + O₂ single turnover reaction entails at least three distinct steps under both low and high pH conditions (Table 2). For a given pH, pairs of reciprocal relaxation times are similar at the two wavelengths monitored in all cases, suggesting that three phases are sufficient to describe the product formation time courses. The slower reciprocal relaxation times decrease with decreasing pH, albeit not proportionally, consistent with the slower formation and longer lifetime observed for the chromophoric intermediate Y257F^{HPCA}_{int2} at pH 5.5 (Figures 3A and B).

The reciprocal relaxation times for the reaction monitored at 425 nm are plotted vs the O₂ concentration in Figure 5. For the reaction at pH 5.5, it is seen that only 1/τ₁ is dependent on O₂ concentration and that the dependence is linear passing through zero (Figure 5A). The linear dependence suggests that 1/τ₁ is at least dominated by the rate constant for the O₂ binding step and the zero intercept suggests that this step is effectively irreversible. If the binding reaction occurs first in the reaction sequence and is irreversible, then 1/τ₁ = k₁ = 4.0 × 10⁴ ± 0.2 M⁻¹ s⁻¹.

At pH 7.5, the fastest reciprocal relaxation time is again linearly dependent on O₂ concentration, but the intercept of the plot is not zero (Figure 5D). This is the expected result if the O₂ binding reaction occurs first and is reversible at this pH value. The forward and reverse rate constants are given by the slope and intercept of the plot respectively (k₁ = 2.7 × 10⁴ ± 0.2 M⁻¹ s⁻¹, k₋₁ = 11.0 ± 0.1 s⁻¹, K_d^{O2} = k₋₁/k₁ ≈ 400 μM). The consequence of a fast reversible first step in the reaction is expected to be a hyperbolic plot for another of the 1/τ vs O₂ plots, as observed in Figure 5E. The y-intercept of this plot is the reverse rate constant k₋₂ for the step following O₂ binding (zero in this case). The plot asymptotically approaches the sum of k₂ + k₋₂, while the K_{app} for the plot is the K_d for the O₂ binding reaction (non-linear fitting gives k₂ = 15.0 ± 0.6 s⁻¹ and K_d^{O2} = 500 ± 40 μM). The irreversible nature of this step would uncouple the third reciprocal relaxation time from the others, so it would be expected to be independent of O₂ concentration and equal to the sum of the forward and reverse rate constants for the third step in the reaction, as observed (k₃ + k₋₃ = 2 ± 0.1 s⁻¹) (Figure 5F). The amplitude for this uncoupled third phase monitored at 350 nm is much larger than those of the others, suggesting that the third step in the reaction is ring-cleavage. If this is the case, then the reaction is irreversible and k₋₃ = 0. The irreversible steps following O₂ association are presumably the explanation for the low observed K_m value for O₂ (Table 1) despite that rather high K_d^{O2} value for complex formation.

Returning to the pH 5.5 data, the occurrence of an initial irreversible O₂ binding step would uncouple 1/τ₂ and 1/τ₃ from O₂ concentration dependence, as observed in Figures 5 B and C). This does not indicate *a priori* that 1/τ₂ and 1/τ₃ are uncoupled from each other, and they may not be if the second reaction step is reversible. However, our previous studies of intermediates in extradiol dioxygenase cycles have shown that the steps in their formation are generally well described as irreversible; attack of an activated oxygen intermediate on substrate to form a covalent alkylperoxo species or subsequent breaking of the O-O bond are unlikely to be reversible processes.^{8,12} Thus, it is likely that 1/τ₂ and 1/τ₃ are equal to rate constants of unique steps. This analysis does not indicate which rate constant is associated with which step, although it is likely that the order established by the pH 7.5 data is maintained (k₂ = 2.6 ± 0.2 s⁻¹ and k₃ = 0.70 ± 0.06 s⁻¹). The assignment can be directly probed by analysis of the extinction coefficient of the chromophoric intermediate (see

Discussion) or by directly trapping the intermediate for quantification using a technique such as Mössbauer spectroscopy, as described below.

Rate-Limiting Step

The rate constants for the reaction cycle steps that can be directly observed are all significantly greater than the k_{cat} value at both pH 7.5 and 5.5. These steps apparently encompass O₂ binding through formation of the product. Consequently, the rate limiting step must be either product release or a step in the substrate binding sequence or both.

Mössbauer Study of the Anaerobic Y257F-HPCA Complex

The anaerobic Y257F-HPCA complex (Y257F_{ES}^{HPCA}) exhibits well-resolved Mössbauer spectra in strong applied magnetic fields, B, a rather rare occurrence for the type of ligand environments afforded by ferrous sites with a 2-His-1-carboxylate facial triad ligand motif. Therefore, it is useful to extract zero field splitting (ZFS), magnetic hyperfine (⁵⁷Fe A-tensor) and electric field gradient (EFG) parameters from the data. Figures 6 and 7 show variable field, variable temperature Mössbauer spectra of Y257F_{ES}^{HPCA}. The zero field spectrum of Figure 6A exhibits a doublet with quadrupole splitting $\Delta E_Q = 3.19$ mm/s and isomer shift $\delta = 1.12$ mm/s, parameters typical of high-spin Fe^{II}. Y257F_{ES}^{HPCA} exhibits a single doublet, in contrast to the HPCA complexes formed with H200N and FeHPCD,¹⁷ which exhibited, for reasons not yet understood, two species. The variable field spectra of Y257F_{ES}^{HPCA} observed at 4.2 K reflect an $S = 2$ spin system for which the two lowest levels form a quasi-doublet with expectation values of the electronic spin, $\langle S \rangle$, that are large in one particular direction (here z) and small in directions perpendicular to z. $\langle S \rangle$, together with the ⁵⁷Fe magnetic hyperfine tensor, **A**, determines the internal magnetic field at the nucleus, $\mathbf{B}_{\text{int}} = -\langle \mathbf{S} \rangle \cdot \mathbf{A} / g_n \beta_n$, which in turn determines the observed magnetic splitting. We have analyzed the spectra of Figures 6 and 7 in the framework of the commonly used $S = 2$ spin Hamiltonian:

$$\mathcal{H} = D \left[S_z^2 - 2 + \left(\frac{E}{D} \right) (S_x^2 - S_y^2) \right] + \beta \vec{S} \cdot \vec{g} \cdot \vec{B} + \vec{S} \cdot \vec{A} \cdot \vec{I} - g_n \beta_n \vec{B} \cdot \vec{I} + \frac{eQV_{zz'}}{12} \left[3I_{z'}^2 - \frac{15}{4} + \eta(I_{x'}^2 - I_{y'}^2) \right] \quad (1)$$

The traceless ZFS tensor (parameters D and E) defines the main molecular frame, (x,y,z). The quadrupole interaction (the last term in eq 1) is written in its conventional form in the frame (x',y',z'). The method of analyzing the spectra follows that described by Zimmermann et al. for protocatechuate 3,4 dioxygenase.²² Our major conclusions are summarized in the following. The ZFS tensor of Y257F-HPCA is nearly rhombic, $E/D = 0.32$. For perfect rhombicity, namely $E/D = 1/3$, the three t_{2g} -derived orbital states would be equally spaced with respect to each other (provided they have the same covalency).²³ The two lowest spin levels of Y257F_{ES}^{HPCA} have $M_S = \pm 2$ heritage (i.e., they would have the exact $M_S = \pm 2$ label in the limit $E/D = 0$). In moderate applied fields, the induced magnetic hyperfine interactions of the spectra of Figures 6B–D depend on the splitting Δ of the “ $M_S = \pm 2$ ” doublet and not on D and E/D separately; where Δ is given by:²²

$$\Delta = 2D [(1 + 3(E/D)^2)^{1/2} - 1] \quad (2)$$

Analysis of the spectra in Figures 6B–D showed that Y257F_{ES}^{HPCA} has $\Delta \cong 3.2 \text{ cm}^{-1}$. This Δ value is much too large for observation of integer spin EPR signals at either X- or Q- band ($h\nu = 0.3 \text{ cm}^{-1}$ at X-band). Further analysis revealed that the EFG tensor of Y257F_{ES}^{HPCA} is

quite axial ($\eta = (V_{x'x'} - V_{y'y'})/V_{z'z'} = 0.20$), that its largest component, $V_{z'z'}$, is positive (hence $\Delta E_Q > 0$), and that z' makes an angle $\beta_{\text{EFG}} \approx 27^\circ$ relative to z . The stated properties are readily extracted from the spectra of Figures 6B–D. The high-energy (right) features of the spectra of Figures 6B and C depend on $g_z A_z$. However, the right hand features of Figure 6D depend only on A_z (for the quoted value of Δ the expectation value $\langle S_z \rangle$ saturates at $\langle S_z \rangle = -2$ independent of g_z), which allowed us to determine $A_z/g_n \beta_n = -6.3$ T. Above 20 K the electronic spin system is in the fast relaxation regime. The 25 K spectrum shown in Figure 7A is reasonably sensitive to D but depends only weakly on E/D . This behavior allowed for fitting of the 25 K spectrum to obtain $D = -11.2 \text{ cm}^{-1}$ which, using the expression for Δ , yielded $E/D = 0.32$.

The simulations shown in Figures 6 and 7 represent the data very well. The spin Hamiltonian parameters of Table 3 will be a useful spectroscopic benchmark for density functional calculations based on the X-ray structure of $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ (see accompanying report). The solution presented in Table 3 is not unique. We have made many attempts to fit the spectra and have found that all reasonable solutions share the following features: D is confined to $(9\text{--}11) \text{ cm}^{-1}$ and, roughly, $0.31 < E/D < 0.36$. β_{EFG} may vary between 20 and 35° , and β_A is between 3 and 10° ($\beta_A = 0$ did not produce good fits). The observation that the EFG and A -tensors have different principal axis systems suggests that the A -tensor has substantial orbital contributions; as the latter are proportional to $(g_i - 2)$, it follows that the g -values cannot be 2.00, as we have arbitrarily assumed. The orbital contributions to $\mathbf{A}$ are expected to be diagonal in (x, y, z) , whereas the spin-dipolar contribution to $\mathbf{A}$ is expected to be diagonal in (x', y', z') , the principal axis system of the EFG tensor. The combination of the orbital and spin dipolar parts determines the principal axis frame of the A -tensor. The software package WMOSS allows group fits to *theoretical* spectra. Thus, if quantum chemical calculations suggest different solutions, researchers can use the solution given here to explore whether particular parameter sets are compatible with the data.

Density functional calculations, combined with a ligand field approach, will relate the spin Hamiltonian parameters to molecular coordinates and delineate the orbitals available for interaction with O_2 ; such studies are in progress. While these calculations are beyond the scope of the present work, the spectra collected here are useful in judging the Mössbauer spectra of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$, presented next.

Mössbauer Spectra of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$

Figure 8 shows 4.2 K Mössbauer spectra recorded for $B = 0$ of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ formed at pH 6.0. The sample for $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ was rapidly quenched 100 ms after mixing with O_2 . The kinetic data suggests that this sample should contain 60% $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$, 20% $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ and 20% $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ (see *Discussion*). The sample for $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ was quenched at 500 ms and, according to the kinetic data, should contain 60% $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$, 20% $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and 20% $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$ ($\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$). Neither sample exhibited an EPR spectrum in either perpendicular or parallel mode. It can be seen that the spectra of the two samples are essentially the same and, moreover, the spectra are close to those seen for the $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$; zero field spectra for $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$, $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ are shown in Figure S3. Clearly, the iron sites of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ are high-spin ferrous, in stark contrast to the Fe^{III} – radical intermediates observed for the early oxy-intermediates of the H200N variant.^{16,17} In order to get the best possible ΔE_Q and δ values for $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ the contributions of $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$

and $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$ were subtracted from the spectra and then the remaining spectra were combined such that the contribution of either $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ or $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ canceled. In this way, we found $\Delta E_Q = 3.02(3)$ mm/s and $\delta = 1.15(2)$ mm/s for $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\Delta E_Q = 3.08(3)$ mm/s and $\delta = 1.18(2)$ mm/s for $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$.

Figure 9 shows 2.0 T spectra of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ (black hash marks) and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ (blue) samples recorded at 4.2 K. For comparison, we show the theoretical curve (red) of the $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ complex. It can be seen that the 2T spectra of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ are indistinguishable within the noise, and that both differ from the spectrum of $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$. Subtraction of the spectrum represented by the red curve from the 2T spectrum of $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ showed that the 100 ms sample could have no more than 15% contribution to the total iron from $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$. Likewise, subtraction of the zero field spectrum of $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$ from the corresponding spectrum of the 500 ms sample showed the end complex can account for no more than 20% of total iron in the 500 ms sample.

The reader may wonder why the ΔE_Q values of Y257F , $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$, $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$, $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ and $\text{Y257F}_{\text{Prod}}^{\text{HPCA}}$ are the same within 6%. The present complexes have a distorted octahedral symmetry for which the three lowest states are combinations of mainly d_{xy} , d_{yz} , and d_{xz} orbitals. It has been shown that any linear combination of these three orbitals (the 5T_2 approximation) yields the same ΔE_Q at 4.2 K as long as there are no major changes in covalency.²⁴ As the states observed here present us with various FeO_5N coordinations, the small variability in ΔE_Q is not surprising.

DISCUSSION

The results described here show that Tyr257 plays an important role in efficient catalysis at several points in the catalytic cycle of FeHPCD. Structural studies indicate that it has two different types of interactions with the substrate.^{2,3,6} First, there is a van der Waals interaction between the Tyr-OH and the C2 carbon of the substrate forcing a slight global deformation to the aromatic ring. Second, the Tyr-OH forms a hydrogen bond to the deprotonated substrate C2-O⁻ in both the anaerobic enzyme substrate complex and the $\text{FeHPCD}_{\text{Int1}}^{4\text{NC}}$ intermediate (Figure 1). The second interaction causes a substantial localized distortion in the normally planar ring. This work complements earlier studies in which the roles of His200 and the nature of its interaction with the second iron-bound substrate, O₂, were examined.^{12,16,17,25} These studies support the hypothesis that the two substrates are connected electronically through the iron and that the transfer of electron density from the catecholic substrate to O₂ is the basis for oxygen activation in this system. The current studies show that the second sphere residues of the iron, specifically His200 and Tyr257, must also work in concert to make the O₂ activation process efficient and specific. Newly recognized aspects of this complex collaboration for catalysis are discussed here.

Kinetic Model for Catalysis

The rate constants assigned for the single turnover reactions at pH 7.5 and 5.5 are shown in Scheme 2A and B, respectively. Figure 10 shows a numerical integration simulation of the single turnover reaction of $\text{Y257F-HPCA} + \text{O}_2$ at pH 5.5 for the model shown in Scheme 2B. The simulation predicts that $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ will accumulate to ~ 64% at 90 ms, and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ will build to ~ 63% at 700 ms. The simulation for the reaction at pH 7.5 predicts

an accumulation of $Y257F_{Int1}^{HPCA}$ of ~ 30% at 50 ms while that of $Y257F_{Int2}^{HPCA}$ is computed to be ~ 55% at 250 ms (simulation not shown). These values together with the known total enzyme concentration can be used to predict the extinction coefficient of $Y257F_{Int2}^{HPCA}$ of $\epsilon_{425} = 10,500 \text{ M}^{-1} \text{ cm}^{-1}$ at each pH value. The values predicted by Model B at pH 5.5 for the intermediate concentrations are similar to those observed in RFQ/Mössbauer samples from a reaction time course at pH 6.0 (Figure 8), supporting the order for the rate constants associated with the second and third steps shown in Scheme 2 (enzyme precipitation at high concentration prevented making pH 5.5 Mössbauer samples).

Chemical Nature of $Y257F_{Int1}^{HPCA}$

$Y257F_{Int1}^{HPCA}$ forms in a second-order reaction between $Y257F$ -HPCA and O_2 , so it is an oxygen complex of some sort. However, it differs from each of the oxygen complexes found thus far for FeHPCD and its variants as summarized in Table 4. For example, $Y257F_{Int1}^{HPCA}$ closely resembles $FeHPCD_{Int1}^{HPCA}$ in most of its characteristics, but these intermediates are clearly quite different because only $Y257F_{Int1}^{HPCA}$ exhibits an O_2 concentration dependence for its formation rate constant. Consequently, $Y257F_{Int1}^{HPCA}$ must represent a species occurring as O_2 binds, while we have proposed that $FeHPCD_{Int1}^{HPCA}$ is a species occurring after irreversible oxygen attack on the substrate.¹⁷ $Y257F_{Int1}^{HPCA}$ could, in principle, be the $SQ^{\bullet}\text{-Fe}^{II}\text{-O}_2^{\bullet-}$ species postulated to be the reactive oxygen-activated species and observed *in crystallo* when a crystal of FeHPCD-4NC is exposed to O_2 .⁶ However, it is illustrated below that the electronic transitions which give rise to the $SQ^{\bullet}$ chromophore are easily detected and not greatly perturbed when the $SQ^{\bullet}$ ligand is exchange coupled to a high-spin $Fe^{III}\text{-(H)peroxo}$ site. This is likely to also be the case for a $SQ^{\bullet}$ ligand bound to an $Fe^{II}\text{-O}_2^{\bullet-}$ site, but there is no precedent in solution for this state to the best of our knowledge. Consequently, the lack of a strong chromophore from $Y257F_{Int1}^{HPCA}$ suggests that this intermediate does not contain a semiquinone or quinone form of the substrate. Since Mössbauer data show that $Y257F_{Int1}^{HPCA}$ contains only Fe^{II} , the lack of a bound $SQ^{\bullet}$ or quinone suggests that the bound oxygen must remain close to the O_2 oxidation state. This would not be expected to be a strong bond, which is in accord with the weak affinity observed here for the complex at pH 7.5 (see below for a discussion of the complex at pH 5.5). It is also possible that O_2 is bound in the active site, but not to the iron (In this case, however, there must be some adjustment in the iron coordination as the Mössbauer spectra of $Y257F_{Int1}^{HPCA}$ differ from those of $Y257F$ -HPCA as shown in Figure 9). This type of complex appears to be an intermediate in the O_2 binding process in FeHPCD and other dioxygenases based on previous transient kinetic studies.^{8,26,27} We propose that $Y257F_{Int1}^{HPCA}$ is most likely an HPCA- $Fe^{II}\text{-O}_2$ complex with minor electron transfer or spin delocalization to the oxygen. The relevance of this conclusion to the role of Tyr257 is discussed below.

Chemical Nature of $Y257F_{Int2}^{HPCA}$

In contrast to $Y257F_{Int1}^{HPCA}$, $Y257F_{Int2}^{HPCA}$ exhibits a relatively intense chromophore at 425 nm and possibly a weak feature near 325 nm. The λ_{max} and intensity of this chromophore is consistent with the spectra observed in the UV-vis region from unbound quinones or semiquinones, albeit with a slightly larger extinction coefficient.¹⁷ In the absence of FeHPCD, incubation of HPCA with a high potential quinone results in an unbound HPCA- $SQ^{\bullet}$ exhibiting a very similar long wavelength spectrum to that observed for $H200N_{Int1}^{HPCA}$ (Figure 11, λ_{max} near 610 for $H200N_{Int1}^{HPCA}$ and 645 nm for HPCA- $SQ^{\bullet}$),¹⁷ suggesting that

the electronic transitions which give rise to the $SQ^{\bullet}$ chromophore are retained when the $SQ^{\bullet}$ ligand is exchange coupled to a high-spin Fe^{III} -(H)peroxo site. This is likely to also be true for a $SQ^{\bullet}$ - Fe^{II} - $O_2^{\bullet-}$ site, since the origin of the semiquinone chromophore is not charge transfer to the iron.

The UV-vis spectrum of $Y257F^{HPCA}_{Int2}$ is missing the low energy UV-vis feature associated with the $HPCA-SQ^{\bullet}$, but it does have a feature similar to that observed for the unbound $HPCA-Q$ (Figure 11, λ_{max} near 425 nm for $Y257F^{HPCA}_{Int2}$ and 395 nm for unbound $HPCA-Q$). Based on this spectrum, $Y257F^{HPCA}_{Int2}$ is unlikely to contain a $HPCA-SQ^{\bullet}$. Mössbauer spectra from a sample expected to contain > 60% $Y257F^{HPCA}_{Int2}$ shows that only Fe^{II} species are present. The absence of Fe^{III} species, the lack of a low-energy band, and the presence of an intense feature near 425 nm suggest that $Y257F^{HPCA}_{Int2}$ is most likely a $HPCA-Q-Fe^{II}$ -(H)peroxo complex.

Origin of Rate Constant Decreases in Reaction Cycle Steps – Mechanistic Significance

The rate constants for intermediate conversion in the catalytic cycle are affected in similar ways by the $Y257F$ mutation as by the use of 4NC as the substrate. We have proposed that 4NC slows the reaction because the electron withdrawing nitro substituent makes electron transfer through the Fe^{II} to the O_2 less favorable.^{8,11,12} This is dramatically observed in the $H200N-4NC$ reaction with O_2 where the $4NC-Fe^{III}-O_2^{\bullet-}$ species persists for hundreds of seconds without attacking the 4NC.¹⁶ In the case of $HPCA$, the electron donating inductive effects of the para substituent will make it much more favorable to donate an electron through the iron to the O_2 , leading to rapid, nearly irreversible binding. The effect of this putative electron transfer will be to give the substrate semiquinone character that would facilitate subsequent attack by the superoxo species formed in the process. However, a radical semiquinone will normally form by delocalizing the unpaired spin on the ring, which would cause the ring to remain essentially planar. Moreover, no position would be preferentially activated for attack by the superoxide, so specificity would result solely from orientation of the superoxo moiety. Stabilization of the $HPCA-C2-O^{\bullet-}$ below the plane of the ring by interaction with $Tyr257$ would serve to not only promote the formation of the semiquinone, and thus electron transfer, but also to localize the radical on $HPCA-C2$. This would activate this position for superoxide attack, thereby accelerating the reaction. It is possible that without this additional stabilization, electron transfer between the substrates does not readily occur, leading to slow kinetics for the same reasons just described for the 4NC reaction.

The natures of $Y257F^{HPCA}_{Int1}$ and $Y257F^{HPCA}_{Int2}$ appear to support the proposal that the rate of electron transfer between substrates is slowed. The discussion above suggests that no electron has transferred from the substrate in $Y257F^{HPCA}_{Int1}$ while in $Y257F^{HPCA}_{Int2}$ most likely two electrons have transferred without attack on the substrate by a putative intermediate superoxo species as occurs in the reaction cycle of the WT enzyme. It may be that without the localized radical and ring distortion caused by $Tyr257$, attack on the ring is much less favorable. It remains unclear whether the attacking species is superoxo or (hydro)peroxo in the wild type enzyme with $HPCA$ as the substrate. While it appears from the current results that the (hydro)peroxo intermediate can go forward to attack the quinone form of the aromatic substrate, this reaction is slow relative to the normal rate of formation of the alkylperoxo intermediate. One possibility is that the electrons from substrate are transferred one at a time, normally leading to a reactive substrate and oxygen radical pair after the first electron is transferred. If the reactivity of this pair is decreased due to lack of stabilization by

Tyr257, then there is time for transfer of the second electron to form the quinone and (hydro)peroxo pair bound to the Fe^{II}.

Basis for pH Effects on O₂ Binding

The binding of O₂ to the iron of FeHPCD is a complex process that is carefully regulated to assure specificity. The current and several past studies show that substrate must bind first to provide the electrons needed to stabilize the Fe-O₂ bond and perhaps to facilitate the release of solvent that blocks the O₂ binding site in the resting enzyme.^{28–31} In the absence of Tyr257, we hypothesize that the supply of electrons to stabilize the Fe-O₂ bond will be compromised, causing the binding process to be slow and reversible. One way the enzyme can counter the reversibility is to protonate His200 which is in hydrogen bonding and charge interaction range of the bound O₂ (Figure 1). In particular, the new positive charge gained by protonating His200 at low pH would stabilize O₂^{•–} character as O₂ binds to the iron. This would not necessarily make the binding process more rapid, but it might serve to slow oxygen release leading to the observed high O₂ affinity.

Roles of Tyr257 in Other Reaction Cycle Steps

The results indicate that the slowest step in the reaction of Y257F is shifted from product formation to either product release or substrate binding. This suggests that Tyr257 may play a role in one or both of these processes. In another branch of the extradiol dioxygenase family typified by *Sphingomonas paucimobilis* SYK-6 protocatechuate 4,5-dioxygenase (LigAB) or *E. coli* 2,3-dihydroxyphenylpropionate 1,2-dioxygenase (MhpB), a histidine is sometimes present in place of Tyr257.³² Mutagenesis and kinetic studies of MhpB indicate that this histidine may play a role as a base catalyst by promoting deprotonation of the substrate during binding with transfer back to the lactone intermediate during ring opening.³³ The structural studies presented in the accompanying report suggest that Tyr257 is not involved in active site interactions that would stabilize a deprotonated form, and thus it is unlikely to act as an active site base.² However, it does participate in key hydrogen bonding and van der Waals interactions with substrate that would favor the anionic form of the substrate C2-hydroxyl. Thus, it may accomplish some of the mechanistically relevant roles attributed to the MhpB histidine through a different strategy. These interactions are absent in Y257F, and this may account for the decreased rate of steps in the substrate binding and/or product release processes.

CONCLUSION

For the reaction of the WT FeHPCD, the oxygen binding, activation, and reaction steps to form the alkylperoxo intermediate of the reaction cycle are complete within the dead time of the stopped flow instrument at 4 °C (~1 ms). In contrast, these steps in the Y257F variant require well over 100 ms to complete. The > 100-fold decrease in observed rate (and rate constants) shows that Tyr257 plays a key role in aiding the ring attack/oxygen insertion steps. The catalytic process does proceed in the absence of Tyr257, encompassing the putative HPCA-Fe^{II}-O₂ and HPCA quinone-Fe^{II}-(H)peroxo intermediates described here, but the decreased rates suggest that these intermediates are not optimized for the most efficient catalytic process.

Figure 1.

Second sphere residues proposed to participate in catalysis. A) FeHPCD_{ES}^{HPCA}, structure of the anaerobic FeHPCD-HPCA substrate complex (PDBID: 1Q0C).³ B) FeHPCD_{Int1}^{4NC}, structure of the oxy complex from the FeHPCD-4NC + O₂ reaction (PDBID: 2IGA, subunit C).⁶ This reaction intermediate is proposed to have a SQ[•]-Fe^{II}-O₂^{•-} electronic structure. The endogenous iron ligands are omitted for clarity.

Figure 2.

Estimation of K_d for HPCA binding to Y257F. The anaerobic substrate complexes were prepared in 200 mM MOPS buffer pH 7.5, 22 °C. 4CC is a weak binding catechol, 4-chlorocatechol. Concentrations: Y257F and FeHPCA, 40 μ M; HPCA, 4NC, and 4CC, 80 μ M when present.

Figure 3.

The Y257F-HPCA + O₂ reaction time-course followed using diode-array detection. Approximately 80 μ M Y257F-HPCA complex was mixed with $\sim$ 500 μ M O₂ at 4 $^{\circ}$ C and pH 7.5 (A) and pH 5.5 (B) (1 cm pathlength). Inset: The reaction time-course monitored with single-wavelength detection at 450 nm.

Figure 4.

The Y257F-HPCA + O₂ reaction time course followed using single-wavelength detection at 450 nm and 350 nm. Approximately 80 μ M Y257F-HPCA complex was mixed with $\sim$ 500 μ M O₂ at 4 $^{\circ}$ C and (A) pH 7.5 or (B) pH 5.5 (1 cm pathlength). The residuals from the fit are plotted on the same absorbance scale as the transient data but displaced for clarity.

Figure 5.

O_2 dependence of the three kinetically competent reciprocal relaxation times from the Y257F-HPCA + O_2 reaction. The data were collected using single wavelength detection at 425 nm following the reaction of $\sim 60 - 80 \mu\text{M}$ Y257F-HPCA complex with varying amounts of O_2 at 4 °C and pH 5.5 (left) or pH 7.5 (right)

Figure 6.

4.2 K Mössbauer spectra of $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$ recorded in parallel applied magnetic fields as indicated. The red curves are spectral simulations, in the slow relaxation limit of the electronic spin, based on the $S = 2$ Hamiltonian of eq 1 using the parameters listed in Table 3.

Figure 7.

6.0 T Mössbauer spectra of Y257F^{HPCA}_{ES} recorded at the temperatures indicated on the left side of the figure. The red curves are spectral simulations, performed in the fast relaxation limit of the electronic spin, using the parameters of Table 3.

Figure 8.

Zero field 4.2 K Mössbauer spectra of $\text{Y257F}_{\text{ES}}^{\text{HPCA}}$, $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ (100 ms sample) and $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ (500 ms sample). Quadrupole splittings and isomer shifts are $\Delta E_Q = 3.02(3)$ mm/s and $\delta = 1.15(2)$ mm/s for $\text{Y257F}_{\text{Int1}}^{\text{HPCA}}$ and $\Delta E_Q = 3.08(3)$ mm/s and $\delta = 1.18(2)$ mm/s for $\text{Y257F}_{\text{Int2}}^{\text{HPCA}}$ (see text).

Figure 9.

2.0 T Mössbauer spectra of Y257F_{Int1}^{HPCA} (black hashed) and Y257F_{Int2}^{HPCA} (blue) recorded at 4.2 K. For comparison is shown the spectral simulation for the enzyme substrate complex, Y257F-HPCA (red, same curve as in Figure 6D).

Figure 10. Simulation of expected time-dependent relative yields for reaction intermediates from the Y257F-HPCA + O₂ reaction at pH 5.5 for the model shown in Scheme 2B.

Figure 11.

Comparison of UV-vis spectra of unbound HPCA quinone and HPCA semiquinone to those of $Y257F^{HPCA}_{Int1}$, $Y257F^{HPCA}_{Int2}$ and $H200N^{HPCA}_{Int1}$. The spectra of $Y257F^{HPCA}_{Int1}$ and $Y257F^{HPCA}_{Int2}$ are derived from the time course of Figure 3. HPCA quinone and HPCA semiquinone were synthesized as described in *Experimental Procedures*. The spectra are scaled arbitrarily to facilitate comparison of UV-vis features.

Scheme 1.

Proposed reaction sequence for extradiol dioxygenases. For the studies described here, R = CH_2COO^- . The numbering system shown is adopted for consistency with studies described in the accompanying report.² The endogenous Fe^{II} ligands are omitted for clarity.

Scheme 2.

Kinetic models for species occurring in the Y257F-HPCA + O₂ single-turnover reaction.

Rate constant are as determined from kinetic analysis of the Y257F-HPCA + O₂ reaction at pH 7.5 (Model A) and pH 5.5 (Model B).

Table 1Steady state parameters for FeHPCD-HPCA and Y257F-HPCA reaction with O₂.^a

Kinetic parameter	Wild type 22 °C pH 7.5	Y257F 22 °C pH 7.5	Y257F 4 °C pH 7.5	Y257F 22 °C pH 5.5
k_{cat} (s ⁻¹)	10.0 ± 1.5	2.70 ± 0.13	0.38 ± 0.07	0.4 ± 0.1
$K_{\text{m}}^{\text{HPCA}}$ (mM)	0.016 ^b	0.26 ± 0.05	0.25 ± 0.05	0.13 ± 0.02
$k_{\text{cat}}/K_{\text{m}}^{\text{HPCA}}$ (mM ⁻¹ s ⁻¹)	625	10.4	1.5	3.1
$K_{\text{m}}^{\text{O}_2}$ (mM)	0.015 ± 0.007	0.08 ± 0.03	0.02 ± 0.01	0.01 ± 0.005
$k_{\text{cat}}/K_{\text{m}}^{\text{O}_2}$ (mM ⁻¹ s ⁻¹)	667	34	19	40

^aReactions were conducted in 200 mM MES or MOPS at pH 5.5 or 7.5, respectively. The buffer is air saturated at either 4 °C or 22 °C. At this O₂ concentration, the reaction is saturated.

^bFrom ref. ¹

Table 2

Reciprocal relaxation times and amplitudes obtained from fitting single wavelength data from the Y257F-HPCA + O₂ reaction at one O₂ concentration.^a

Reciprocal relaxation time number	450 nm pH 5.5 s ⁻¹ (amp)	350 nm pH 5.5 s ⁻¹ (amp)	450 nm pH 7.5 s ⁻¹ (amp)	350 nm pH 7.5 s ⁻¹ (amp)
1	13 (0.09)	10 (-0.1)	21 ^b (0.07) ^c	21 (0.017)
2	2.9 (-0.41)	2.9 (0.12)	5.5 (-0.40)	5.0 (0.18)
3	0.75 (0.30)	0.65 (-0.41)	1.8 (0.27)	2.2 (-0.91)
4	0.002 (-0.08)	0.002 (-0.08)	0.03 (-0.18)	0.03 (-0.25)

^aFitting to a 4 summed exponential equation by nonlinear regression using Pro Data viewer software available with Applied Photophysics SX series stopped-flow. 80 μM Y257F-HPCA complex was mixed with 500 μM O₂ at 4 °C and pH 7.5, (1 cm pathlength, 2 mm slit width).

^bThe fitting error for all data in a single experimental run with at least 5 repeated trials is less than ± 3 %. For the experiment repeated using different enzyme batches over multiple days, the error is approximately ± 10%.

^cThe sign of an amplitude from exponential fitting is the opposite of the observed direction of change.

Table 3

$S=2$ Spin Hamiltonian parameters of Y257F-HPCA evaluated using eq 1

$D(\text{cm}^{-1}) = -11.2 \text{ cm}^{-1}$	$A_x/g_g\beta_n = -22 \text{ T}$	$\Delta E_Q = +3.19 \text{ mm/s}$
$E/D = 0.32$	$A_y/g_g\beta_n \sim -29 \text{ T}$	$\eta = 0.20$
$g_x = 2.00^a$	$A_z/g_g\beta_n = -6.3 \text{ T}$	$(\alpha\beta\gamma)_{\text{EFG}}^b = (160, 27, 0)^\circ$
$g_y = 2.00$		$(\alpha\beta\gamma)_A^b = (98, 6.5, 76)^\circ$
$g_z = 2.00$	$\delta = 1.12 \text{ mm/s}$	

^a g -values were fixed to $g = 2.00$.

^b $(\alpha\beta\gamma)_{\text{EFG}}$ and $(\alpha\beta\gamma)_A$ are the Euler angles that rotate the EFG- and A - tensor into (x,y,z). The simulations are more sensitive to β than to α and γ .
