To the Editor: Our recent demonstration¹ that proximally linked ‘protective’ agents can yield substantial improvements in the performance of the cyanine fluorophore Cy5 motivated us to develop more photostable fluorophores spanning the visible spectrum. Such fluorophores would enable a broad range of applications and experimental demands. Here, using strategies identical to those previously described¹, we show that marked enhancements in performance can also be achieved for other widely used members of the cyanine class, Cy2, Cy3, Cy3.5, Cy5.5 and Cy7 (Fig. 1a) when coupled to individual cyclooctatetraene (COT), nitrobenzylalcohol (NBA) and Trolox molecules (Supplementary Methods).

We quantified each fluorophore’s performance (Fig. 1b) using single-molecule fluorescence imaging techniques¹. This method gives access to a number of salient properties of individual fluorophores under continuous laser excitation including the apparent brightness of fluorescent states and the rates at which transient and permanent nonfluorescent states are entered (‘blinking’ and ‘photobleaching’, respectively). These measures can then be used to assess the average number of photons emitted by a fluorophore before entering a dark state (the duration of fluorescence (t_{on}) $\times$ mean fluorescence intensity) and the effective signal-to-noise ratio (SNR) of fluorescence, a parameter that reports on the variance in a fluorophore’s photon emission rate (Fig. 1b). These data reveal that the performance of each cyanine-class fluorophore tested is enhanced when linked to single protective agents. Notably, these positive effects varied substantially for each fluorophore type. For instance, each of the COT-linked fluorophores showed dramatic enhancements in overall performance. For Cy2-COT, we observed an ~25-fold increase in the number of photons emitted before a dark-state transition. For Cy3-COT and Cy3.5-COT, this parameter changed very little, but the SNR of fluorescence for both molecules increased approximately four- to fivefold. Cy5.5-

COT and Cy7-COT showed 50- and 70-fold increases, respectively, in the number of photons emitted before entering a dark state. Consequently, the average Cy5.5-COT and Cy7-COT molecule could be continuously imaged for ~3 min at an SNR >7:1 (Fig. 1c). Consistent with our previous work¹, we observed only modest improvements for most NBA-linked fluorophores. However, we observed an almost 70-fold enhancement of photon count for Cy7-NBA. Trolox, which shows the most favorable impact on the performance of the Cy5 fluorophore¹, also had relatively modest beneficial effects for the other cyanine-class fluorophores.

These data provide compelling evidence that the strategy of proximally linking protective agents to the fluorogenic center to enhance its performance can be generalized. However, the high variability in a yield of benefits observed for the cyanine class suggests the need for a deeper understanding of how protective agents provide photostabilization. Plausible mechanisms for mediating enhancements in fluorophore performance include cycles of reduction and oxidation, triplet-triplet energy transfer and exciplex-type relaxation². As suggested by Tinnefeld and Cordes³, the enhancements in performance of Trolox-linked fluorophores may arise through favorable reductionoxidation cycles with the fluorogenic center. However, the results we obtained suggest that the benefits of such a mechanism may be restricted to the Cy5 and Cy5.5 fluorophores, which perhaps reflects an appropriate matching of their redox potentials. By contrast, we observed more substantial and general enhancements for each of the COT-linked cyanine fluorophores. Given the estimated triplet energy and redox potential of COT (unpublished data) and COT's propensity for triplet-triplet energy transfer⁴, these findings suggest that a triplet-triplet energy transfer mechanism may be the most generally effective means for cyanine fluorophore photostabilization. Forward progress toward quantifying the relative weights and impacts of each pathway for distinct fluorophores will enable additional improvements in the activities of these known protective agents. Insights of this kind may also aid the discovery of new compounds and the implementation of new strategies to meet the specific demands of distinct fluorophore types. Ultimately, continued efforts on these fronts may yield strategies that can be generalized for tailoring fluorophore performance for a broad array of distinct experimental demands.
