Abstract

Background—Premenstrual dysphoric disorder (PMDD) is a chronic condition that significantly affects a woman's well-being on a monthly basis. Although co-occurrence of PMDD and major depressive disorder (MDD) is common, most studies examine whether women with PMDD are at risk for depression and investigations of PMDD in depressed women are scant. Therefore, the present study examined rates of PMDD in young depressed women.

Methods—PMDD was assessed using a structured clinical interview (SCID-PMDD) in a sample of 164 young women with (n=85) and without (n=79) any history of depression.

Results—Rates of PMDD were elevated among women with MDD in this sample. This result held true regardless of participants' MDD status (current, lifetime or past history-only symptoms of MDD) and regardless of whether all or most DSM-IV-TR PMDD criteria were met.

Limitations—Sample size in the present study was relatively small, and daily diary data were not available to confirm a PMDD diagnosis.

Conclusions—The current study highlights the need for clinicians to assess for PMDD in young female patients with major depression. Depressed women experiencing the added physical and psychological burden of PMDD may have a more severe disease course, and future studies will need to identify appropriate treatments for this subset of depressed women.

Keywords

pre-menstrual dysphoric disorder; major depressive disorder; comorbidity

BACKGROUND

Premenstrual dysphoric disorder (PMDD) is a chronic condition that significantly affects well-being during the reproductive years. The pattern of symptoms of PMDD is linked to the menstrual cycle, with the onset of symptoms in the late luteal phase and the symptom offset shortly after the beginning of menses (Freeman, 2004). PMDD is currently classified in the Diagnostic and Statistical Manual of Mental Disorders (DSM-4th ed.; American Psychiatric Association, 2000) as a depressive disorder not otherwise specified, and based on existing research evidence, the Mood Disorders Work Group for DSM-5 proposed to move PMDD to the position of a full-category in DSM-5 (Epperson et al., 2012). Based on DSM-IV criteria, at least five of 11 symptoms are necessary for diagnosis, with at least one of the symptoms being related to mood. Symptoms include depressed mood, anxiety/tension, affective lability, anger/irritability, decreased interest, difficulty concentrating, fatigue, appetite changes, sleep difficulties, feeling out of control and physical symptoms (APA, 2000). PMDD is associated with significant personal and economic costs, increased work absenteeism, reduced work productivity (Heinemann et al., 2012), and reduced quality of life (Heinemann et al., 2010; Yang et al., 2010; Yang et al., 2008),

Sex differences in depression rates (Sprock and Yoder, 1997; Wolk and Weissman, 1995) suggest that women might be at increased risk for psychiatric illnesses as a result of naturally changing hormonal levels during their reproductive cycle (Miller et al., 2009). In addition to high rates of pregnancy, post-partum, and peri-menopausal depression (Soares and Zitek, 2008), up to 85% of menstruating women exhibit one or more menstrual cycle-related symptom, 20–40% report Premenstrual Syndrome (PMS), and 2–9% report PMDD (Clayton, 2008).

The comorbidity rates between major depressive disorder (MDD) and PMDD are high, spanning a range of 30–70% (Endicott, 1994). Both MDD (Kendler et al., 2006) and PMDD (Treloar et al., 2002) have heritable risk, suggesting the possibility that both PMDD and MDD share common risk mechanisms (Accortt et al., 2006; Accortt et al. 2011b).

Despite a significant overlap in symptoms between PMDD and MDD, the monthly recurrent and predictable pattern of symptom onset and offset is a key feature that distinguishes PMDD from other mood disorders (Endicott et al., 1999). Women with PMDD are also more likely to report physical symptoms such as bloating and breast tenderness (Di Giulio and Reissing, 2006; Hartlage et al., 2012) and irritability (Angst et al., 2001; Landen and Eriksson, 2003) as opposed to depressed mood (Bhatia and Bhatia, 2002). Additionally, treatment response to medications differs as women with PMDD report alleviation of symptoms almost immediately after administration of the serotonin reuptake inhibitors (SRIs; Steiner et al., 2005; Steiner et al., 2008; Yonkers et al., 2006).

To date, a majority of studies have focused on whether women with PMDD are at risk for depression (Endicott and Halbreich, 1988; Pearlstein et al., 1990; Yonkers et al., 1997). There are very few investigations of the prevalence of premenstrual symptoms in depressed women (Halbreich and Endicott, 1985; Hsiao et al., 2004; Miyaoka et al., 2011), none of which provided interview-based assessments of PMDD. To address this gap, the present study examined rates of PMDD in a sample of young depressed women. Examining PMDD in the context of depression is important as these women may experience a more severe course of illness (Pilver et al., 2013) and have unique characteristics that influence treatment response.

METHODS

Participant Selection

Participants with and without MDD were recruited in a larger study of depression (Stewart et al., 2010). All female subjects were assessed to determine PMDD status using a structured clinical interview (Accortt et al., 2011a). Participants with disorders other than PMDD, MDD, and dysthymia were excluded, as were any using prescription and psychotropic medications (see Accortt et al., 2011b, for full exclusion criteria). Intake interviews with eligible participants were conducted by graduate-level clinicians, who administered the Hamilton Depression Rating Scale (HDRS; Hamilton, 1967), Structured Clinical Interview for the DSM-IV (SCID; First et al., 1997), and SCID-PMDD. The SCID-PMDD is a reliable structured PMDD interview created from the DSM-IV-TR PMDD criteria, modeled after the SCID format (see Accortt et al., 2011a, for description and psychometric properties).

Population Details

Out of 177 women recruited between 2004 and 2007, 7 women dropped out of the study, 6 women did not complete the PMDD interview for various reasons, resulting in 164 women included in this study. All participants were university undergraduate students with an average age of 18.9 years (± 1.2 s. d., range of 18 to 25). Table 1 presents demographic and birth control status details for the sample by diagnostic status. Use of birth control pills (BCP) was unrelated to PMDD status (see Table 1).

Participant Grouping

Thirty women endorsing sufficient pre-menstrual symptoms were invited to participate in the daily diary monitoring (Daily Record of Severity of Problems, DRSP; Endicott et al., 2006). Because participants were not compensated for their participation, compliance was poor, and conclusive evidence of 2 consecutive cycles with late luteal phase mood worsening was not available. Five participants in whom partial diary data were able to disconfirm at least one cycle of late luteal mood worsening were removed from the PMDD experimental group. In the remaining group of 25 interview identified participants, 13 participants (8% of the entire sample) met DSM-IV-TR criteria for PMDD, endorsing five or more of the DSM-IV-TR items with symptoms that lasted four or more days. Twelve participants (7% of the entire sample) endorsed five or more of the DSM-IV-TR items, but did not fully meet the time specification criteria listed in the DSM-IV-TR because their symptoms lasted less than four days. These 12 women, together with the women meeting the strict criteria (totaling 25 participants), were classified as Spectrum PMDD. Participants were categorized in terms of MDD (lifetime and current) using the SCID. It is worth noting that the Mood Disorders Work Group for DSM-5 proposed revising the timing criterion such that symptoms need not be present for most of the week prior to the onset of menses, instead allowing the presence of symptoms during any point that week to be sufficient (Epperson et al., 2012). Under the proposed revised criteria, both Strict PMDD and Spectrum PMDD women in the present study would be diagnosed with PMDD.

RESULTS

PMDD prevalence was 8% for the Strict PMDD classification (13/164), and an additional 7% (12/164) met DSM-IV-TR criteria for PMDD (including the impairment criterion) but symptoms did not last “most of the week,” totaling 15% who were thus considered among the Spectrum PMDD classification.

Co-occurrence of Diagnoses

The co-occurrence of MDD and PMDD was examined to determine if any history of MDD was associated with elevated rates of PMDD. To characterize the co-occurrence of PMDD classification and major depression status, a series of Chi Square tests were carried out to test the independence of PMDD classification and MDD status. Analyses were run separately for classifications of Strict PMDD (13 PMDD+ and 151 PMDD-) and Spectrum PMDD (25 PMDD+, 139 PMDD-), and also separately for Current MDD (37 MDD+, 127 MDD-), and participants with any History of depression (current or past MDD status) called Lifetime MDD status (85 MDD+, 79 MDD-). Moreover, to assess whether there was an increased likelihood of PMDD in women with past history of MDD, unconfounded by current MDD or dysthymia symptoms that could account for the overlap, the rates of PMDD were compared between never depressed women (79 Lifetime MDD-) and euthymic women with past history of MDD (45 Euthymic MDD Hx +). For this last analysis, 13 of the 25 Spectrum PMDD cases remained and 6 of the 13 Strict PMDD cases remained in the analyses. Figure 1 shows that in general terms, MDD diagnoses are associated with a higher likelihood of PMDD diagnoses.

Significant relationships emerged between Lifetime MDD and Strict PMDD ($X^2(1, N = 164) = 9.3, p < 0.05$), Current MDD and Strict PMDD ($X^2(1, N = 164) = 7.9, p < 0.05$), and currently euthymic women and Strict PMDD ($X^2(1, N = 127) = 6.1, p < 0.05$). In each case, MDD women had a higher rate of PMDD than non MDD women.

Significant relationships also emerged between Lifetime MDD and Spectrum PMDD ($X^2(1, N = 164) = 9.4, p < 0.05$), Current MDD and Spectrum PMDD ($X^2(1, N = 164) = 7.8, p < 0.05$) and currently euthymic women and Strict PMDD ($X^2(1, N = 123) = 4.0, p < 0.05$). In each case, MDD women had a higher rate of PMDD than non MDD women.

Therefore, regardless of whether MDD was defined in terms of current, lifetime, or past-history only status, for both Strict and Spectrum PMDD classifications, rates of PMDD were elevated among women with MDD in this sample.

DISCUSSION

Extending previous findings on co-occurrence of MDD and PMDD, this study found that college-age women with MDD tend to have elevated rates of PMDD. Increased prevalence of PMDD was consistent across depression diagnoses (Current, Lifetime, & Euthymic Hx+) for women meeting Strict PMDD criteria as well as for women meeting all of the DSM-IV-TR criteria except for timing of symptoms. These findings refute the possibility that currently depressed women are simply endorsing pre-menstrual symptoms due to current depressive symptoms (i.e., “I feel depressed, so ‘everything’ is wrong with me”) as women positive for history of depression but currently not experiencing MDD (Euthymic MDD Hx +) had rates of PMDD that were elevated compared to never depressed women. These findings are consistent with the questionnaire-based reports of elevated rates of PMDD in depressed women in Japan (Miyaoaka et al., 2011), although the prevalence rates in the present study are somewhat lower, as might be expected from the use of a structured interview.

The present results suggest that PMDD prevalence is relatively high among those with any history of MDD. Therefore, MDD patients should be carefully assessed for PMDD. This is especially important for treatment considerations (Epperson et al., 2012), as depressed women with greater premenstrual symptoms have a more severe disease course (Hartlage et al., 2004), including an elevated risk for non-fatal suicidal behaviors (Pilver et al., 2013).

Having comorbid PMDD and MDD may potentially increase the severity of suicidal symptoms and subsequently, the likelihood of suicide attempts.

The age of participants in this study is 18–25 years, so these women have not had a long period of risk for either MDD or PMDD. As an early-onset sample, these women may have more lifetime mood instability and more lifetime episodes than those with later onset, and therefore, may endure the emotional burden of mood fluctuations for a significant portion of their lives. For these reasons it is imperative to begin investigating symptomatology, course and risk for PMDD (and other mood disorders) at an earlier age.

Strengths, Limitations, and Future Directions

Limitations of the present study are a relatively small sample of women and unavailability of 2 months of diary data to confirm the PMDD diagnosis. Nonetheless, this study represents an advance over self-report studies by providing a reliable structured interview diagnosis for women with PMDD (Accortt et al., 2011a). Future studies with incentives for diary completion will be needed to determine what percentage of women meeting PMDD criteria according to the interview are confirmed with diary data.

Even in the absence of the diary data, the current study provides clinically relevant information on elevated rates of PMDD symptoms in young women with an early onset of depressive diagnoses, and underscores the need for clinicians to assess for PMDD in young female MDD patients. Further investigations of PMDD in women with mood disorders will help identify appropriate treatments for those experiencing the added significant psychological and physical burden of PMDD in addition to the existing mood instability associated with other mood disorders.

Acknowledgments

This research was supported in part by grants from the National Institutes of Health (R01-MH066902) and the National Alliance for Research on Schizophrenia and Depression (NARSAD) to John Allen. The authors wish to thank Eliza Ferguson, Jamie Velo, Dara Halpern, Craig Santerre, Amanda Brody, Jay Hegde and many research assistants for their help on this project

Role of funding source: The funding source (NIH) had no role in study design, in the collection, analysis and interpretation of data, in the writing of the report, or in the decision to submit the paper for publication.
