Abstract

A growing list of proteins, including the α -sheet-rich SH3 domain, is known to transiently populate a compact α -helical intermediate before settling into the native structure. Examples have been discovered in cryogenic solvent as well as by pressure jumps. Earlier studies of lambda repressor mutants showed that transient states with excess helix are robust in an all- α protein. Here we extend a previous study of src SH3 domain to two new SH3 sequences, phosphatidylinositol 3-kinase (PI3K) and a Fyn mutant, to see how robust such helix-rich transients are to sequence variations in this α -sheet fold. We quantify helical structure by circular dichroism (CD), protein compactness by small angle X-ray scattering (SAXS), and transient helical populations by cryo-stopped flow CD. Our results show that transient compact helix-rich intermediates are easily accessible on the folding landscape of different SH3 domains. In molecular dynamics simulations, force field errors are often blamed for transient non-native structure. We suggest that experimental examples of very fast α -rich transient misfolding could become a more subtle test for further force field improvements than observation of the native state alone.

Keywords

circular dichroism; small angle X-ray scattering; cryosolvent; secondary structure; protein folding

Introduction

The formation of α -helical structure from a polypeptide chain begins with a localized nucleation event between residues i and $i + 4$.¹ Thus it is plausible that non-native helical structure could form transiently during the earliest stages of protein folding, only to dissolve when longer range native contacts of even lower free energy are made. Residual helical

structure exists in denatured states,² fragments α -helix and β -sheet proteins,^{3,4} and 'equilibrium intermediates' stabilized in acidic solution.⁵ It is also seen in simulations, even with force fields that have relatively low helix propensity.⁶

Excess β -helix content has been reported during the earliest stages of protein folding. In particular, cryogenic solvent conditions have tuned the free energy landscape to promote transient helix formation in β -lactoglobulin,⁷⁻⁹ src SH3 domain,¹⁰ the FHA domains of Rad53 and Ki67,¹¹ two sequences of ubiquitin,^{12,13} and two β -6-85 sequences.^{14,15} In the case of the five helix bundle β -6-85, we were able to tune the amount of transient helix by introducing helix-destabilizing residues, but the helix-rich transients were not eliminated.

SH3 domains are β -sheet proteins containing two anti-parallel β -sheets connected by various-length loops (Fig. 1).¹⁶ The src SH3 domain has been studied in particular detail. The structure formed in its transition state in room temperature solvent is known (central β -sheet),^{17,18} but the transition state structure can be altered substantially by circular permutation.¹⁹ Dasgupta and Udgaonkar detected a rapidly formed compact folding intermediate, showing that the early stages of assembly are more complex than previously thought.²⁰ Under cryogenic solvent conditions, src SH3 domain formed a transient β -helix-rich intermediate before folding to the native state.¹⁰ The helix-rich intermediate is a compact globular state: its radius of gyration ($R_g \approx 1.9$ nm) is closer to the native state (1.5 nm) than to the denatured state (2.7 nm).

Here we study whether two sequence variants of the SH3 fold also show a helical burst phase under cryogenic stopped flow conditions. In an all-helical protein like β -6-85, or an α/β protein such as ubiquitin, helical propensity turned out to be robust, but is it for a β -sheet protein? We look in detail at the PI3K SH3 domain, and at a new mutant of Fyn SH3 domain. The two new sequences are compared to SH3 domains studied in the past in Table 1. We chose the Fyn SH3 mutant to study the effect of a small sequence difference relative to SH3 sequences previously studied in cryosolvent. We chose PI3K because its sequence is very different from other SH3 sequences previously studied in cryogenic solvent, but folding studies exist. Guijarro *et al.* initiated the folding kinetics of the PI3K SH3 domain by guanidine hydrochloride (GuHCl) jump and detected it by real-time one-dimensional ¹H nuclear magnetic resonance (NMR) and several optical spectroscopies at 6 and 20 °C.²¹ They showed that all probes monitored the same slow phase. Dasgupta and Udgaonkar reported that the initial collapse of the PI3K SH3 domain polypeptide chain is completed within sub-milliseconds.²⁰ They initiated the reaction by stopped-flow and continuous-flow and detected it by fluorescence resonance energy transfer (FRET) experiments at 25 °C.²⁰ However, these studies were not designed to detect fast formation of secondary structure.

If both PI3K and mutant Fyn SH3 domains also form β -helix-rich compact folding intermediates, then the formation of transient helix structure would appear to be quite robust for this β -sheet-rich fold. SH3 domain then joins the ranks of proteins whose sequence variants have compact non-native states with excess helical structure that lie low enough on the free energy landscape to be stabilized by cryogenic folding conditions.

Molecular dynamics simulations have also shown that helical transients form easily during the early stages of folding.²²⁻²⁴ This is frequently blamed on force field errors, and indeed there is evidence for such 'super-helicity' of force fields used to fold a protein to the *in silico* minimum free energy.²³ However, the experiments described here, as well as the earlier studies referenced above, provide evidence that non-native helical traps can be formed very rapidly in experiments. Further evidence for this is offered by recent pressure jump experiments on β -6-85, also interpreted in terms of transient helical overshoots.²⁵

These results could be useful for testing force fields at a finer level of mechanistic detail than the current paradigm of native structure and average folding/unfolding rates.²⁶ While many small proteins are apparent two-state folders, their folding barriers are quite small (typically 2–10 $k_B T$), and may just barely ‘hide’ free energy landscape roughness, which takes the form of transiently populated non-native structural ensembles. The detection of such transient structures by experiment and molecular dynamics simulations could lead to the next level of refinement and validation of force fields used for protein folding calculations.

Methods

Proteins

The PI3K SH3 domain was expressed in *E. coli* and purified as described.²⁷ The Fyn SH3 domain mutant (Table 1) was expressed in *E. coli* and purified as described.²⁸ Hereafter, the mutant is denoted as just “Fyn mutant.”

Equilibrium CD

The samples of PI3K and Fyn mutant were prepared in 50 mM sodium phosphate buffer at pH 6 with various concentrations of GuHCl in the presence of 45% ethylene glycol unless otherwise noted. GuHCl is of ultra pure reagent grade from ICN Biomedicals Inc. (Lot No. 3814J). The concentration of GuHCl was calibrated by refractive index measurements.^{29,30} The temperature was controlled within ± 1 °C by a recirculating refrigerator. The concentration of both SH3 domains was less than 130 μ M. CD measurements were performed at various temperatures with a spectropolarimeter specially designed by Unisoku Inc. for cryogenic operation. Cuvettes of 1 mm path-length were used for all measurements.

Kinetic refolding: instrument and dead time

The stopped flow instrument was constructed for use with high viscosity solutions at low temperature in collaboration with Unisoku Inc.³¹ Its dead time was estimated to be *ca.* 6 ms by the reduction reaction of 2,6-dichloroindophenol by ascorbic acid³² at 4 °C and –28 °C. For SAXS measurements, dead time was limited by the data sampling rate of 200 ms.

Kinetic refolding: tyrosine and tryptophan fluorescence

Refolding was measured by diluting protein in GuHCl buffer with excess GuHCl-free buffer. The cryogenic buffer was made with 50 mM sodium phosphate in the absence ($T > 4$ °C) or presence ($T = 4$ °C) of 45% ethylene glycol. One volume of protein in 5 M GuHCl buffer was mixed with 6 volumes of buffer, thus giving 0.7 M GuHCl after mixing. A 50 mM sodium phosphate buffer at pH 6 was used to prepare all solutions. The final concentration of PI3K SH3 domain was < 40 μ M, for Fyn mutant < 70 μ M.

Fluorescence was monitored with a specially designed optical fiber of less than 1 mm thickness, which was inserted into the stopped flow observation cell. Tyrosine fluorescence was excited at 268 nm and integrated at wavelengths above 305 nm with a cutoff filter. Tryptophan fluorescence was excited at 295 nm and integrated at wavelengths above 325 nm with a cutoff filter.

Kinetic refolding: CD

The same conditions were used as for fluorescence, with final concentration of PI3K SH3 domain 10 – 30 μ M and Fyn mutant 30 – 50 μ M. The refolding process was monitored by CD at 222 ± 2 nm ($[\theta]_{222}$) at several temperatures. The averaged data was normalized to give molar ellipticity.

At each condition, in addition to the refolding experiment, two more experiments were always done: 1) Mixing the unfolded protein in the GuHCl buffer with the same GuHCl buffer gives us the initial CD level. 2) Letting the solution relax for 5 to 20 minutes gives us the final CD level. In many cases, the first data point of the refolding experiments already differs from the initial level, indicating the existence of a burst phase. Measured ellipticities were reliable to $\pm 200 \text{ deg cm}^2 \text{ dmol}^{-1}$ during the 10 s time scale of kinetics measurements, although drifts of 500 to 1000 $\text{deg cm}^2 \text{ dmol}^{-1}$ were observed over 5–20 minutes. However, all burst phases have amplitudes significantly larger than even this slow drift.

SAXS

The SAXS experiment monitors the decreasing size of the protein coil during the refolding process.³³ SAXS experiments were performed at beamline 15A of the Photon Factory at KEK (Tsukuba, Japan).^{34,35} The X-ray wavelength was $\lambda = 1.504 \text{ \AA}$. A CCD detector was used for both kinetic and static measurements.^{36,37} Time-resolved SAXS measurements of PI3K SH3 domain were performed at $-5 \text{ }^\circ\text{C}$ as described elsewhere.^{38,39}

SAXS measurements were also performed at the Biophysics Collaborative Access Team Beamline of the Advanced Photon Source at Argonne National Laboratory (Argonne, IL).⁴⁰ The X-ray wavelength was $\lambda = 1.0 \text{ \AA}$. An Avix CCD detector was used for kinetic measurements as described previously.²⁸ Time-resolved SAXS measurements of Fyn mutant were performed at $-28 \text{ }^\circ\text{C}$. The dead time was 0.1 to 0.2 s.

Helium gas was flowed in and around the observation cell in order to prevent frost from forming on the window. X-ray scattering data were collected for both protein solution and the corresponding buffer to allow background subtraction. The scattering data of the buffer were subtracted from those of the protein solution. X-ray scattering data were analyzed by the Guinier approximation, assuming that the logarithm of the scattering intensity depends linearly on q^2 , where $q = 4\pi \sin \theta / \lambda$ and θ is half of the scattering angle.⁴¹ The linear Guinier region was fitted to obtain R_g , where the value of $R_g q$ is < 1.3 to satisfy the Guinier condition.

Equilibrium experiments were performed using a static-flow cell⁴² at $-4 \text{ }^\circ\text{C}$ to prevent radiation damage of the proteins. Concentrations of PI3K and Fyn SH3 domain were less than $300 \text{ }\mu\text{M}$.

Results

Comparison of PI3K kinetics with previous measurements

We observed the slow apparent two-state refolding of PI3K SH3 domain at room temperature to confirm consistency of our data with previous results.^{20,21} Fig. 1 shows kinetic refolding signals by intrinsic tyrosine fluorescence of PI3K SH3 domain at $26 \text{ }^\circ\text{C}$. The signal fits a single-exponential decay with rate coefficient $k_{\text{obs}} = 0.032 \pm 0.004 \text{ s}^{-1}$. In the kinetic refolding experiments of intrinsic tyrosine fluorescence by Guijarro and co-workers,²¹ two rate coefficients were reported: $0.0585 \pm 0.0016 \text{ s}^{-1}$ and $0.0169 \pm 0.0003 \text{ s}^{-1}$, for two-state folding of different proline isomeric forms. Their average rate coefficient matches well our single value. (Our signal-to-noise ratio did not require a double-exponential fit.)

GuHCl-induced equilibrium unfolding of PI3K SH3 domain

We next performed equilibrium unfolding experiments at subzero temperatures to determine optimal conditions for refolding kinetics. Experiments were done at pH 6 in the presence of

ethylene glycol as anti-freeze (see Methods).⁹ We checked the effect of ethylene glycol on the conformation of PI3K SH3 domain by circular dichroism (CD) spectroscopy. CD ellipticities at 222 nm ($[\theta]_{222}$) were within 5% from 0 to 90% ethylene glycol. This result for these solvent conditions is consistent with our previous work.^{9–13,15}

Fig. 2A shows far-UV CD spectra of PI3K SH3 domain at two temperatures with and without GuHCl. The two 0 M GuHCl spectra are nearly identical, so the secondary structure of PI3K SH3 domain remains stable from -20 to 4 °C. They are also very similar to spectra of the native state at pH 7.2 at 25 °C reported by Okishio *et al.*²⁷ The two 5 M GuHCl spectra show slightly different random coil shapes, so residual secondary structure is temperature-dependent. PI3K SH3 domain is extensively denatured by 5 M GuHCl in 45% ethylene glycol regardless of temperature. (Guanidine absorption precludes spectral collection below 210 nm.)

The guanidine denaturation curves at 222 nm ($[\theta]_{222}$) are shown in Fig. 2B. The mid-points lie at $c_M = 3.08 \pm 0.04$ M (-20 °C) and 3.26 ± 0.06 M, so denaturant jumps from 5 to 0.7 M GuHCl should allow for complete refolding of the PI3K SH3 domain.

The guanidine denaturation curve was also detected by SAXS at 4 °C. R_g values were calculated from Guinier plots of each scattering curve, and plotted in Fig. 3A. The R_g values of PI3K are in good agreement with those for src SH3 domain from reference¹⁰: 14.5 ± 0.6 Å (folded PI3K) vs. 14.6 Å (folded src) and 27.5 ± 0.7 Å (denatured PI3K) vs. 26.7 Å (denatured src). The SAXS data yielded a $c_M = 2.7 \pm 0.5$ M GuHCl where the radius of gyration increased cooperatively. The large uncertainty of c_M arises because the SAXS data was sampled at 0.5 M increments of denaturant.

The CD and SAXS fits were obtained with a sigmoid model (two-state, native = N and unfolded = U). The signal S is represented by⁷

$$S(c) = \frac{S_N + S_U e^{-m(c-c_M)}}{1 + e^{-m(c-c_M)}} \quad (1)$$

Here m represents the cooperativity of the transition, and S_N and S_U are the signal values of the N and U states, represented as linear baselines. Note that the smaller midpoint $c_M = 2.7 \pm 0.5$ M obtained at 4 °C by SAXS agrees within experimental uncertainty with the more accurate value of 3.26 ± 0.06 M obtained by CD. The mid-points both for CD and SAXS lie at about 3 M, so denaturant jumps from 5 to 0.7 M GuHCl between -20 and 4 °C should allow for complete refolding of the PI3K SH3 domain.

Our c_M in ethylene glycol buffer lies 1.3 M higher than the result reported by Guijarro *et al.* and detected by intrinsic tyrosine fluorescence (c_M is 1.4 M).²¹ As they measured at room temperature without ethylene glycol, this suggests PI3K SH3 domain is more stable at lower temperatures in the presence of 45% ethylene glycol. We have reported that mutants of ubiquitin, FHA1 domain of Rad53 and lambda repressor proteins were also slightly more stable in the presence of cryosolvent.^{11,13,15}

Refolding kinetics of PI3K SH3 in cryosolvent

We carried out time-resolved refolding experiments by GuHCl-jump from 5 to 0.7 M with our cryo-stopped flow apparatus. Secondary structure was detected by CD and protein compactness was detected by SAXS at subzero temperatures (Figs. 3B and 4).

Time-resolved R_g values after the GuHCl-jump are shown in Fig. 3B. R_g dropped from the unfolded value of 27.5 Å (Fig. 4A) to 17.2 ± 1.0 Å within our dead time of 200 ms. This radius is 19% larger than that of the native state (14.6 ± 0.6 Å), but much smaller than that of the denatured state (27.5 ± 0.7 Å). Therefore any transient intermediate of PI3K SH3 domain is nearly as compact as the native state. We averaged Kratky plots over the 0 to 1 s time window. Albeit noisy, the plot has a peak (Fig. 3C), further suggesting that the transient intermediate is a compact globular state.

In Fig. 4, secondary structure is monitored during refolding of PI3K SH3 domain. The refolding trace at -5 °C shows a large burst phase in the CD spectrum at 222 nm (Table 2), followed by a single exponential decay towards the native value. The transient ellipticity is about twice the magnitude of the native CD signal (*ca.* -1600 deg cm² dmol⁻¹). This suggests that PI3K SH3 domain forms a transient α -helix-rich intermediate in < 6 ms (our dead time), followed by slower interconversion to the native state (directly or *via* less compact conformations). We also performed kinetic refolding CD experiments at -20 °C. The α -helical burst was even larger at the lower temperature (Table 2).

Together, the kinetic refolding experiments in cryogenic solvent detected by SAXS and CD show that the PI3K SH3 domain at low temperature populates a compact α -helix-rich state before folding to the native state on a much longer time scale. The radius of the transient intermediate is only 19% larger than that of the native state.

Kinetic refolding of Fyn mutant in cryosolvent

We also studied a new Fyn mutant, which is much more similar to previous SH3 domains studied under cryogenic solvent conditions.¹⁰ All experiments at low temperatures were done at pH 6 in the presence of 45% ethylene glycol as anti-freeze (see Methods).

Fig. 5A shows circular dichroism spectra of Fyn mutant in 0 M and 5 M GuHCl buffer. Its CD spectra in 0 or 0.7 M GuHCl at 4 °C are almost identical to that of the native wild-type Fyn SH3 domain reported by Di Nardo *et al.*⁴³ This indicates that Fyn SH3 domain remains folded in 0.7 M GuHCl at cryogenic temperatures, just like PI3K SH3 domain. In contrast, the CD spectrum in 5 M GuHCl is nearly zero at 222 nm.

We measured refolding kinetics by jumping the Fyn mutant from 5 to 0.7 M GuHCl at -28 °C (Fig. 5B). The signal jumps from a molar ellipticity ≈ 0 to -5600 deg cm² dmol⁻¹ in < 6 ms. Following the burst phase, the native state CD signal is recovered in ≈ 1 second. The resolvable refolding kinetics was not a single-exponential process. Two rate coefficients of 17 ± 3 s⁻¹ and 2.5 ± 0.5 s⁻¹ fitted the data within measurement uncertainty. The two-step process is consistent with the previously published kinetics of Fyn SH3 domain pseudo wild type W37F.¹⁰

To further characterize the double-exponential refolding subsequent to the burst phase, we also monitored tryptophan fluorescence under the same conditions as in the CD experiments (Fig. 5B). The resolvable refolding signal for both CD and fluorescence detection could be fitted globally to the same double exponential (Table 2). Unlike the CD signal, fluorescence is non-monotonic, clearly showing the need for a double-exponential fit. Before reaching the native state the Fyn mutant proceeds through a hyperfluorescent stage, which has been interpreted as a signature of a highly flexible native-like conformation in other proteins.⁴⁴

We also measured SAXS of Fyn SH3 domain (Fig. 6). Guinier plots in 0 M and 4 M GuHCl at 4 °C are shown in Fig. 6B. R_g was 14.6 ± 0.8 Å and 27.3 ± 3.9 Å, respectively, confirming that the Fyn mutant is denatured in > 4 M GuHCl. The 14.6 Å value is in good agreement with the native value of the protein reported previously.²⁸ The 27.3 Å is also in

good agreement with the denatured values of src and PI3K SH3 domain as described above.¹⁰

Kinetic refolding at -28°C and monitored by SAXS was initiated by cryo-stopped flow (Fig. 6A). Within 0.1 to 0.2 seconds, the R_g approaches the native value.

The CD, fluorescence and SAXS data suggest a similar picture for the Fyn mutant as for the PI3K SH3 domain. First, the protein rapidly collapses and forms excess helical structure (< 6 ms). Then the CD signal at 222 nm approaches the smaller native magnitude. Unlike PI3K SH3 domain, the Fyn mutant recovers from the compact excess helical state in two steps. Thus, even neglecting the rapid collapse and secondary structure formation at < 6 ms, the Fyn mutant, like the pseudo wild type, is not an apparent two-state folder.

Discussion

Quite an array of data has accumulated to suggest that the formation of compact α -helical intermediates during protein folding is commonplace.^{7,9–15,45,46} Even though such intermediates are not populated at physiological temperature, they are easily elicited in cryogenic solvent, proving that they are not much higher in free energy than the native state. The cryogenic conditions do not necessarily elicit helical intermediates by destabilizing the native state: in Fig. 2A the PI3K SH3 domain denaturation midpoints are very similar at 4 and -20°C .

The transient population of compact helix-rich states early on during folding should not be surprising: Rapid protein collapse is driven by hydrophobicity (albeit less so at low temperatures⁴⁷), and α -helical formation requires only local (i to $i + 4$) contacts, which can be explored by the unfolded chain on very fast time scales.

In this context, it is worth noting that a β -sheet protein has been reported that forms two different structures from the same sequence in equilibrium (one with only β -sheet, the other with some helix).⁴⁸ The more α -helix-rich structure has a different biological function than the more β -rich structure. Such proteins may well have evolved starting from transient helix-rich states that lie at low free energy relative to the native state.

SH3 domain is the latest entry in the series of proteins that can form α -helix rich compact intermediates: three different sequences or mutants of this domain (Fyn, src and PI3K) transiently populate states with excess helical structure (Table 2). The 222 nm ellipticities of the burst phase of src SH3 domain,¹⁰ Fyn mutant and PI3K SH3 domain all had values much greater in magnitude than the native state. The transient helix-rich intermediate “ I_1 ” is not specific to any variant.

This is not to say that all three sequences fold in the same way: src SH3 domain and Fyn SH3 domain mutants have a very similar sequence (Table 1). Their helical intermediates have similar compactness and excess helical content (Table 2). The PI3K sequence is quite different. Even though its AGADIR helical score is slightly higher (Table 1),⁴⁹ the burst phase of PI3K SH3 domain is significantly smaller than that of the other two SH3 domains. The Fyn mutant and PI3K SH3 domain also differ in other ways. The latter folds in a single exponential step to the native state after the helical burst that populates I_1 . The Fyn mutant populates an additional intermediate I_2 with more native-like helix content, and folds faster overall. All observations are consistent with the following kinetic scheme for SH3 domain folding: From the GuHCl denatured state U, I_1 is a compact helix-rich intermediate rapidly populated in cryosolvent. From I_1 , the native state N forms slowly, either in one step by losing the non-native helical structure of I_1 , or through a second intermediate I_2 . Whether I_1 is a trap that has to unfold completely before acquiring native structure, or just partly off-

pathway because excess helix can be lost without increasing the radius of gyration too much, it is easily accessible on the free energy landscape

Evolutionary selection should filter out states like I_1 if they reduce protein function or lead to aggregation. Clearly, evolution of SH3 domain proteins has not selected against such states strongly: they are populated easily during folding by adding a carbohydrate-like co-solute (ethylene glycol), and/or a $0.1 k_B T$ decrease of the available thermal energy. Indeed, the interior of a cell is not an aqueous buffer, but filled with carbohydrates, nucleic acids and other crowders that influence protein stability and kinetics;⁵⁰ a 45% ethylene glycol/water mixture is likely no further removed from the cytoplasmic environment than the aqueous phosphate buffer commonly used for *in vitro* protein folding studies.

In silico, metastable helical states are also commonly observed. For example, the β -sheet WW domain was shown to fold to a helical state by the CHARMM force field, and the force field was modified to better represent β -sheet hydrogen bonding to correct this.^{23,51} Ref. 24 reports further recent results and reviews some of this literature. In simulations, helical bursts are generally considered a nuisance, but our results here, and those for other proteins, indicate just how subtle the nuisance is: Helical states really exist that lie low on the free energy landscape, and force fields will have to be delicately balanced to place them at the appropriate free energy. More data on metastable states containing non-native helix could provide benchmarks for a further level of force field refinement, which takes into account not just native and denatured ensembles, but also metastable ensembles populated during folding.

Recently, several computational papers have suggested functional properties of kinetic helical intermediates. Chikenji and Kikuchi⁵² concluded from a simple polar-non-polar model that non-native α helix restricts the conformational search and guides folding of β -lactoglobulin. Mohanty *et al.*⁵³ reported that the N-terminus of Top7-CFr initially forms a helical extension to hide a native β -sheet that could lead to harmful aggregation during folding. Such reports point out that non-native helix could assist folding instead of simply delaying it.

While our cryogenic conditions foster rapid formation of helix-rich intermediates, folding to the native state is generally very slow (seconds) in cryogenic experiments. Microsecond pressure jumps hold promise for showing that formation of excess helical structure can occur on a microsecond time scale, where comparison with simulation is currently feasible.²⁵

Conclusion

Combined with literature results, four different sequences of SH3 domain, including the PI3K sequence that is very different from src- and Fyn-based sequences, all show transient helical populations in cryogenic ethylene glycol/water solvent. At the same time, this solvent only slightly stabilizes the proteins overall. Subtle tuning of these proteins' free energy landscapes (by a few $k_B T$) sufficiently stabilizes helix over sheet structure for the former to become transiently populated: the fast kinetics of local contacts briefly dominates over the more favorable free energy of native structure. Non-native 'overshoots' will be useful for calibrating molecular dynamics force fields' helix/sheet propensities, if such 'overshoots', known from our data to occur in < 6 ms, are resolved on the sub-millisecond time scale.

Acknowledgments

The authors are grateful to Professor Stuart L. Schreiber of Harvard University for kindly providing the expression vector containing PI3K SH3 domain, and to Dr. Masayuki Morita of Kansai Medical University for kindly helping with *E. coli* expression. We thank Dr. Liang Guo at Argonne National Laboratory helpful assistance in setting up the beam line for experiments, and Charles Dumont for help with data collection. This study was supported by a Grant-in-Aid for Scientific Research (No.20540400) from the Ministry of Education, Culture, Sports, Science and Technology. M.G. and S.J.K. were supported by National Institutes of Health grant R01-GM093318. Time on BioCAT-18, managed by Prof. Thomas Irving, was supported by proposal GUP-6360 of the Advanced Photon Source at the Argonne National Laboratory. SAXS measurements were performed under proposal number 2006G407 and 2008G684 of the Photon Factory.

Fig. 1. Generic SH3 fold ribbon structure and intrinsic tyrosine fluorescence of PI3K SH3 domain refolding by GuHCl-jump at 26 °C (aqueous buffer without ethylene glycol). The solid curve is a single exponential fit. The rate constant was $0.032 \pm 0.004 \text{ s}^{-1}$.

Fig. 2.

GuHCl-induced unfolding of PI3K SH3 domain monitored by CD at 4 and -20 °C in 45% wethylene glycol aqueous buffer. (A) Far-UV CD spectra of PI3K SH3 domain with and without GuHCl denaturant. In the short wavelength region with 5 M GuHCl, the data are not shown due to the strong absorption by GuHCl. (B) Unfolding transitions of PI3K SH3 domain on GuHCl concentrations monitored by $[\theta]_{222}$. The solid lines are fits to the cooperative model in eq. 1: $c_M = 3.26 \pm 0.06 \text{ M}$ and $m = 7.80 \pm 0.93 \text{ M}^{-1}$ at 4 °C, and $c_M = 3.08 \pm 0.04 \text{ M}$ and $m = 8.28 \pm 0.66 \text{ M}^{-1}$ at -20 °C.

Fig. 3.

GuHCl-induced unfolding and refolding of PI3K SH3 domain monitored by X-ray solution scattering in 45% ethylene glycol aqueous buffer. (A) Dependence of R_g on GuHCl concentration at 4 °C; the solid line is a fit to the cooperative model in eq. (1). The fitted thermodynamic parameters are $m = 17 \pm 4 \text{ M}^{-1}$ and $c_M = 2.7 \pm 0.5 \text{ M}$. (B) GuHCl concentration jump by the cryo-stopped flow method at -5 °C, on the same y-scale as (A). R_g changed from the unfolded value of 27.5 Å to 17.2 Å within the dead time of the apparatus. (C) Kratky plot for data from (B) averaged from 0 to 1 s shows a broad peak (the solid line is a smoothed version of the same data).

Fig. 4. Kinetic refolding experiments of PI3K SH3 domain at -5°C in aqueous ethylene glycol buffer. The reaction was initiated by cryo-stopped flow from 5 to 0.7 M GuHCl, and monitored by $[\theta]_{222}$, the circular dichroism signal at 222 nm. The black curve is the single exponential fit, also shown on the split time axis (see table 2 for all kinetic rate coefficients).

Fig. 5. GuHCl-induced unfolding and refolding of Fyn mutant in 45% ethylene glycol aqueous buffer. (A) Far-UV CD spectra of the native (0 M GuHCl) and denatured (5 M GuHCl) states of Fyn mutant at 4 °C. In the short wavelength region of the 5 M GuHCl CD spectrum, the data are not shown due to the strong absorption of GuHCl. The arrow at 222 nm indicates the kinetic probe wavelength. (B) Refolding of Fyn mutant monitored by CD (θ_{222}) and tryptophan fluorescence at -28 °C. The GuHCl concentration was jumped from 5 M to 0.7 M. Double-exponential functions with the same rate coefficients but different amplitudes were fitted globally to the CD and fluorescence data (solid lines, see Table 2 for values of the rate coefficients).

Fig. 6.

X-ray solution scattering experiments of Fyn SH3 domain in aqueous ethylene glycol buffer. (A) Refolding of Fyn mutant by cryo-stopped flow SAXS at -28 °C. R_g decreases to the native value within 0.1 to 0.2 s. Native and unfolded R_g values were obtained by equilibrium experiments. (B) Guinier plots of the native (0 M GuHCl) and denatured (4 M GuHCl) state of Fyn SH3 domain at 4 °C at equilibrium. The R_g values of the native and denatured state were 14.6 ± 0.8 Å and 27.3 ± 3.9 Å, respectively.

Table 1

Comparison of protein sequences and AGADIR (helix propensity) scores. Fyn mutations are shown in red, highly conserved residues in yellow.
