Abstract

It has been well realized that the dependence of chemical shift anisotropy (CSA) tensors on the amino acid sequence, secondary structure, dynamics and electrostatic interactions can be utilized in the structural and dynamic studies of proteins by NMR spectroscopy. In addition, CSA tensors could also be utilized to measure the structural interactions between proteins in a protein-protein complex. To this end, here we report the experimentally measured backbone amide-¹⁵N CSA tensors for a membrane-bound 16.7-kDa full-length rabbit cytochrome-b₅ (cytb₅), in complexation with a 55.8-kDa microsomal rabbit cytochrome P450 2B4 (cytP4502B4). The ¹⁵N-CSAs, determined using the ¹⁵N CSA/¹⁵N-¹H dipolar coupling transverse cross-correlated rates, for free cytb₅ are compared with that for the cytb₅ bound to cytP4502B4. An overall increase in backbone amide-¹⁵N transverse cross-correlated rates for the cytb₅ residues in the cytb₅-cytP450 complex was observed as compared to the free cytb₅ residues. Due to fast spin-spin relaxation (*T*₂) and subsequent broadening of the signals in the complex, we were able to measure amide-¹⁵N CSAs only for 48 residues of cytb₅ as compared to 84 residues of free cytb₅. We observed a change in ¹⁵N CSA for most residues of cytb₅ in the complex, when compared to free cytb₅, suggesting a dynamic interaction between the oppositely charged surfaces of anionic cytb₅ and cationic cytP450. The mean values of ¹⁵N CSA determined for residues in helical, sheet and turn regions of cytb₅ in the complex are -184.5, -146.8, and -146.2 ppm, respectively, with an overall average value of -165.5 ppm (excluding the values from residues in more flexible termini). The measured CSA value for residues in helical conformation is slightly larger as compared to previously reported values. This may be attributed to the paramagnetic effect from Fe(III) of the heme in cytb₅, which is similar to our previously reported values for the free cytb₅.

Keywords

Chemical Shift Anisotropy (CSA) tensor; membrane protein; cytochrome-b₅ (cytb₅); cytochrome P450 (cytP450); CSA/dipolar coupling transverse cross-correlated rates

Introduction

There is a growing interest in determining high-resolution structure and dynamics of biomolecules by NMR spectroscopy. Most biological functions in a cell are controlled by proteins, where a vast majority of proteins interact with one another to form protein-protein complexes that are essential for many biological activities. Protein-protein interactions are mediated through a combination of van der Waals forces, salt bridges, and hydrogen bonding and hydrophobic interactions at a specific binding domain of each protein. The strength of binding is influenced by the size, shape and secondary structure of the binding domains. Recent advances in NMR methodology and instrumentation have provided new approaches for the characterization of these interactions at the atomic-level. The interaction between the local electronic environment and the nucleus, known as a chemical shift anisotropy (CSA) tensor, has been widely used to investigate the structure¹⁻³ and dynamics⁴⁻⁶ of biomolecules by both solid-state and solution NMR methods. In addition, the structural and dynamic changes due to a protein-protein complex formation could also be studied using well-characterized chemical shift tensors. Computational methods using quantum chemical calculations⁷⁻²³ have also been developed to study the variation of chemical shift tensors. Several solid-state NMR methods have been used to determine CSA tensors²⁴ from solids that are site specifically labeled with an isotope (e.g., ¹⁵N or ¹³C) such as static CSA powder patterns,²⁵⁻²⁷ aligned samples,²⁸ 2D separated-local-field (SLF) experiments,^{29,30} magic angle spinning (MAS) spectra,³¹⁻³⁵ recoupling techniques,^{36,37} and the gold standard single-crystal studies.³⁸ However, these methods are less applied due to severe spectral overlap for non-selectively (or uniformly) labeled large proteins. On the other hand, this difficulty can be overcome by studying these proteins in solution. Individual components of CSA tensors could not be determined from peak positions in solution as anisotropic interactions are averaged out due to fast tumbling of molecules. Relaxation studies³⁹⁻⁴⁹ using CSA-dipolar cross-correlated rate measurements^{50,51} are generally implemented to determine CSA values in solution, mostly by measuring the differential line widths of the doublet components obtained in HSQC-IPAP (HSQC: heteronuclear single quantum coherence; IPAP: in-phase anti-phase).⁵²⁻⁵⁶ A recent study reported the internal dynamics of the homotrimeric HIV-1 viral coat protein gp41 in a membrane environment from amide-¹⁵N relaxation (R_1 and $R_1\rho$) relaxation rates and ¹⁵N NOE in combination with transverse CSA-dipolar coupling cross-correlated relaxation rate measurements.⁵⁷ Theoretical studies based on a model-free method and molecular dynamics simulations have also been used to study the dynamics of ribonuclease HI (RNase H) and Rho-GTPase Binding Domain (RBD) of Plexin-B1 using amide-¹⁵N relaxation data.^{58,59} Backbone amide-¹⁵N CSA tensors are very sensitive to backbone torsion angles/secondary structure, amino acid sequence, intra and inter residue hydrogen bonding interaction, intra-residue angle, side chain chemistry, electrostatic interactions and solvent effect.^{13,60-67} Because of this reason, it is a daunting task to accurately and precisely determine amide-¹⁵N CSA as compared to ¹³C CSA.

In this study, we have determined backbone amide-¹⁵N CSA tensors for the 16.7-kDa membrane-bound full-length rabbit cytb₅ in a ~70-kDa complex, comprised of microsomal rabbit cytP450B4 (55.8-kDa) and cytb₅, incorporated in micelles using solution NMR spectroscopy. CytP450 is a heme containing transmembrane protein (anchored to the membrane by the N-terminal hydrophobic helix),^{68,69} which is particularly abundant in both plant and animal tissues and play important roles in enzyme kinetics in a variety of biochemical and physiological processes.⁷⁰ Cytb₅, anchored to the membrane by the C-terminal helix,⁷¹ controls the rate of catalysis of cytP450.⁷² Cytb₅ and cytP450 reductase (CPR) act as redox partners of cytP450 to provide electrons for the catalytic reaction where one atom of activated molecular oxygen is inserted to the substrate S, [SH+O₂+NAD(P)H SOH+H₂O+NAD(P)⁺], using two protons from water and two electrons from NAD(P)H.

Although there has been a significant progress towards unraveling NMR structure and dynamics of smaller proteins, our understanding of structure related biological function of larger proteins such as cytP4502B4 and its interaction with other proteins using NMR as a tool still remains a massive task, mainly due to poor sample stability, spectral resolution and sensitivity. We recently reported the first full-length membrane-bound structure of rabbit cytb₅ (PDB 2M33) determined using a combination of the 2D HIMSELF static solid-state NMR experiments on cytb₅ incorporated in magnetically-aligned bicelles and solution NMR experiments on cytb₅ incorporated in isotropic bicelles (or detergent micelles)⁷² (Figure 1A). This study also presented the structure of a highly dynamic electron-transfer complex formed between a full-length membrane-bound cytb₅ and its redox partner cytP450 using experimentally derived NMR constraints and mutagenesis data (Figure 1B). In the absence of NMR structure for cytP4502B4, we made use of a uniformly-labeled cytb₅ resonances in the IPAP spectra to study its complexation with unlabeled cytP4502B4. Amide-¹⁵N CSA tensors determined from cytb₅ in the cytb₅-cytP450 complex are compared with those obtained from free cytb₅.

Experimental Section

Cytochromes, b₅ and P450, were biologically expressed and purified as explained in our previous publication.⁷² ⁷²H-dodecylphosphocoline (DPC-D38) and D₂O were purchased from Cambridge Isotope Laboratories (Andover, MA). Glycerol and buffer components used in NMR experiments were purchased from Sigma-Aldrich and Roche Applied Science. The functional form of cytP450 and the cytb₅-cytP450 complex were determined from activity assays of cytb₅ and cytP4502B4, and carbon monoxide (CO) spectra of cytP4502B4.⁷²

NMR experiments

A 5 mm Shigemi tube containing equimolar ratio (1:1) of a 0.2 mM ferric cytb₅ uniformly labeled with ¹³C, ²H and ¹⁵N isotopes and unlabeled ferric cytP450 in a 100 mM KPi buffer at pH 7.4, 150 mM DPC, 5% glycerol and 10% D₂O at 25°C was used in all NMR experiments. 2D ¹H/¹⁵N SOFAST-HMQC spectra were obtained to test the stability of micelles containing the complex as a function of time. These experiments revealed that the sample was stable for about 28 hours, and started to change after that as indicated by the appearance of multiple peaks and changes in the chemical shift frequency of resonances. We carried out CSA measurements for only those residues for which the chemical shift values did not change even after the completion of measurements. All measurements were carried out on a Bruker 900 MHz NMR spectrometer operating with ¹H and ¹⁵N resonance frequencies of 899.799 and 91.186 MHz, respectively, using a cryoprobe.

Backbone amide-¹⁵N relaxation measurements

The amide-¹⁵N transverse relaxation rate (R_2) measurements were performed on a full-length U-¹⁵N, ¹³C, ²H labeled cytb₅ in the cytb₅-cytP450 complex incorporated in DPC micelles. We collected a time series of ¹⁵N HSQC spectra for the determination of ¹⁵N transverse spin-spin relaxation time (T_2). T_2 measurements were achieved by Carr-Purcell Meiboom-Gill (CPMG)⁷³ spin-echo experiments with relaxation delays of 7.2, 14.4, 28.8, 43.2, 72.0, 100.8, 115.2 and 158.4 ms (with duplicate points for 14.4 and 43.2 ms). In the CPMG pulse sequence, the delays between the 180° pulses were set to 0.9 ms. 256 t_1 increments were used to obtain 2048 × 256 complex data points with 24 scans, 16 dummy scans and 1s recycle delay; duplicate points for two of the relaxation delays were recorded for estimation of errors.

The amide-¹⁵N transverse cross-correlated rate (ρ_{xy}) measurements were accomplished by using proton coupled ¹H/¹⁵N HSQC-IPAP experiments.^{53,56} The IPAP spectra were

collected in an interleaved manner as pseudo-3D experiments with first 2D-plane corresponding to *in-phase* (IP) and second plane to *anti-phase* (AP) spectra. The relaxation delay ($\tau = 1/2J_{N-H}$, with J_{N-H} representing one bond scalar coupling) values were set to 10.64, 15.96, 21.28, 26.60 and 31.92 ms. The same number of scans was used for the *in-phase* and *anti-phase* experiments for a given relaxation delay, while it was varied from 96 for the smallest delay to 368 for the largest delay to compensate for the loss of signal intensity due to a large relaxation delay in the IPAP pulse sequence. NMRpipe⁷⁴ was used for NMR data processing and the subsequent addition/subtraction of *in-phase* and *anti-phase* spectra, whereas peak assignments were done using Sparky.⁷⁵

Results and discussion

Cytb₅ is a 16.7-kDa membrane-bound electron transfer protein consisting of 134 amino acid residues (Figure 1A). It contains a structured N-terminal water-soluble domain (residues 1-90) bound to a paramagnetic heme unit, a transmembrane helical domain (residues 106-126), and an unstructured ~14-residue long linker region (residues 91-104) that connects the transmembrane and heme domains. An overlay of 2D ¹⁵N-¹H TROSY-HSQC spectra of U-¹⁵N, ¹³C, ²H labeled full-length rabbit cytb₅ - in the absence and the presence of cytP450 - incorporated in perdeuterated DPC detergent micelles at 25°C are presented in Figure 2. The well resolved amide-NH resonances from the soluble domain and the linker region of cytb₅ dominates the ¹⁵N-¹H TROSY-HSQC spectra. Due to fast spin-spin relaxation, resonances from the transmembrane region of the protein were not observed. There are no notable changes in the chemical shift values for amide-NH resonances of cytb₅ upon complexation with cytP450 (Figure 2). The average chemical shift perturbations in the amide-NH resonances observed for the residues of cytb₅ as reported in our previous study⁷² was found to be relatively smaller in magnitude (< 0.01 ppm) with a wide spread distribution over a large area of cytb₅ indicating no prominent change in the tertiary structure of cytb₅ upon binding to cytP450.

Comparison of backbone amide-¹⁵N transverse relaxation rates for cytb₅ in the cytb₅-cytP450 complex

Amide-¹⁵N transverse relaxation rates (R_2) for the full-length U-¹⁵N, ¹³C, ²H labeled cytb₅ in the cytb₅-cytP450 complex incorporated in DPC micelles were measured and compared with the values obtained from cytb₅ in the absence of cytP450 (Figure 3). The residues with a fitting error greater than ~18% are not included in the R_2 analysis (refer to Table S1 in the Supporting Information for R_2 values). The average R_2 value for a full-length cytb₅ (residues K7-L104) in the complex cytb₅-cytP450 is found to be $28.0 \pm 3.4 \text{ s}^{-1}$. The measured R_2 value for cytb₅ in the complex is higher than the average R_2 value ($21.6 \pm 1.7 \text{ s}^{-1}$) obtained for free cytb₅. A large average fitting error for cytb₅ in the cytb₅-cytP450 complex, in comparison to free cytb₅, is probably due to the formation of a dynamic complex. The overall increase in the average R_2 value of cytb₅ in the cytb₅-cytP450 complex indicates a reduced mobility of cytb₅ upon complexation with cytP450. Our previous study,⁷² suggested that the dynamic interaction between cytb₅ and cytP450 proceed through the formation of many 'encounter complexes', which are often assumed to be only transiently formed; though the encounter complexes may represent a significant fraction of sample population. The driving force behind the formation of these encounter complexes is the long-range electrostatic interaction between the two oppositely charged surfaces (anionic and cationic surfaces of cytb₅ and cytP450, respectively). This conclusion was derived from the small average isotropic chemical shift perturbations observed upon the complex formation. While the populations of cytb₅ in the free and the bound-state have not been determined in this report, the overall effect of 'transiently formed complexes' is clearly visible from the broadening of NMR signals. NMR line broadening is often described on the basis of an increase in the spin-spin relaxation rate (R_2) of amino-acid residues. The R_2 rates have

contributions from molecular motions and/or orientations (described by global correlation time) governed by dipolar coupling and CSA interactions, and chemical exchange between different states. The fraction of encounter complexes between cytb₅ and cytP450 in the sample would increase the ensemble averaged global correlation time observed for the free cytb₅. Consequently, transverse relaxation rates (R_2) of cytb₅ in the cytb₅-cytP450 complex will increase in comparison to the free cytb₅; this is clearly reflected from a reduction in the signal intensity in the 2D ^{15}N - ^1H HSQC spectrum. In addition, the presence of free and the bound states of cytb₅ would also mean a significant chemical exchange between the two states. It is noteworthy to mention here that without the proper quantitative estimation of the free and bound-states of cytb₅, it is not possible to describe the above effects as minor or major contributions. Relaxation dispersion measurements can reveal the time scale, populations and the chemical shift differences of the species involved in the exchange. Because of the concentration (< 0.2 mM), poor stability of the cytb₅-cytP450 complex sample and the weak intensity of the signals, such experiments were not attempted.

Based on the R_2 values, the differential dynamics of N, C-termini, linker region and soluble domain of the full-length cytb₅ upon complexation with cytP450 could be monitored. N-terminal (K7-D8) and the linker region (L92-K94, M96-L99 and T102-D104) residues show significantly smaller R_2 values (13.9 s^{-1} and 25.6 s^{-1} in the complex; 10.5 s^{-1} and 16.8 s^{-1} in the free state) in comparison to the compact soluble domain (V9-R89) R_2 values (29.3 s^{-1} in the complex and 23.4 s^{-1} in the free state). This observation suggests a high mobility for the N-terminal residues (small R_2 values) in comparison to the linker region residues and the rest of the soluble domain of cytb₅ both in the free as well as in the complex samples. In addition, a small average R_2 value observed for the linker region residues in comparison to the compact soluble domain of cytb₅ - both in the free and bound states - suggests that residues in this region are more flexible. The small R_2 values for N-terminal residues are characteristic for the ends of both folded and unfolded proteins. The observed high flexibility of the linker region could be a possible reason for its ability to provide the directional freedom required for an efficient complex formation with its redox partners such as cytP450. It is important to point out that many residues of cytb₅ show a significant increase in R_2 values upon binding to cytP450 in comparison to free cytb₅. This could be attributed to the oppositely charged surfaces of the two proteins, which mutually interact to form multiple transient dynamic-encounter complexes as reported.⁷² The residues (K77-H85) exhibit a large change in R_2 values. This could possibly be due to a change in the internal motion for these residues upon binding to cytP450 as they are located near to the more flexible linker region. Similarly, residues (K10, Y12 and L14) located near to highly mobile N-terminal of the cytb₅ in the complex show increased dynamics based on a significant change in R_2 values. Residues W27-I29 and G56-D58 belonging to two parallel beta-sheets of cytb₅, wherein the residues are experiencing direct and indirect H-bonding interactions, also show a significant change in R_2 values in the bound-state of the complex. This is attributed to a change in the orientation of the tryptophan ring of cytb₅ upon complexation with cytP450. Consequently, other residues in close proximity with W27 in parallel beta-sheets are also affected resulting in the observed variation in the R_2 values.

Measurement of backbone amide- ^{15}N CSA/dipolar coupling transverse cross-correlated rate for cytb₅ in the cytb₅-cytP450 complex

We measured ^{15}N CSA/dipolar coupling transverse cross-correlated rates for various residues of cytb₅ in the cytb₅-cytP450 complex using the 2D $^1\text{H}/^{15}\text{N}$ HSQC type IPAP method as described by Fushman et al.^{53,56} A small region with resolved in-phase and anti-phase ^{15}N doublet components of the proton-coupled ^{15}N - ^1H HSQC (IPAP) spectrum are shown in Figure 4. Simplified sum (IP+ AP) and difference (IP- AP) spectra were obtained by subsequent addition of the up-field ($I_{up, 2I_y S_z + I_y}$) and subtraction of the down-

field ($I_{dn,2I_yS_z-I_y}$) components of the in-phase and anti-phase doublets, respectively. To compensate for the loss of signal and to obtain a complete removal of unwanted signals, a scaling factor = 1.2 was applied to the anti-phase spectrum before its addition or subtraction to the in-phase spectrum.

The transverse cross-correlated rate measurement depends on the ratio of signal intensities of difference (up-field) and sum (down-field) spectra that decays mono exponentially with an increase in the relaxation delay. Nitrogen-15 transverse cross-correlated rates (ρ_{xy}) were measured by fitting the mono-exponential decay curves to an empirical relation for the intensity ratio, $I_{up,2I_yS_z+I_y}/I_{dn,2I_yS_z-I_y} = Ce^{-4\rho_{xy}\tau}$.^{53,56} τ is the relaxation delay, and C is the ratio of signal intensity decay functions associated with up-field and down-field intensities which was kept as a variable along with ρ_{xy} while fitting the curves. Representative decay curves for residues T13, T70 and R73 of cytb₅ in the complex cytb₅-cytP450 are shown in Figure 5.

Comparison of backbone amide-¹⁵N CSA/dipolar coupling transverse cross-correlated rates for free and P450-bound cytb₅ in micelles

The backbone amide-¹⁵N transverse cross-correlated rates (ρ_{xy}) determined from the best-fitting mono-exponential decay curves for various residues of cytb₅ in the cytb₅-cytP450 complex are plotted in Figure 6 and are compared with the values obtained from free cytb₅. We have omitted residues L28, K39, E48, N62 and S76, belonging to the compact soluble domain (V9-R89) of cytb₅, from further analysis as these residues are associated with a fitting error greater than ~15% (refer to Table S2 in the Supporting Information for the ρ_{xy} values). The average ρ_{xy} value for the compact soluble domain (V9-H85) of the full-length cytb₅ in the cytb₅-cytP450 complex is 17.9 s⁻¹ in comparison to 15.1 s⁻¹ for the free cytb₅. An overall increase in ρ_{xy} values for cytb₅ in the complex suggests a reduction in the global molecular tumbling as compared to free cytb₅, which corroborates our results based on R_2 values. It is important to note here that even if binding of cytb₅ with cytP450 reduces its overall mobility, still different secondary structural elements of the protein complex could undergo differential change in their local motion. This is also obvious from Figure 6 where the change in ρ_{xy} for cytb₅ in the complex as compared to free cytb₅ is observed throughout the amino acid chain of the protein suggesting a change in the internal motion of the residues of cytb₅ upon binding to cytP450. Analogous to free cytb₅, ρ_{xy} values for cytb₅ residues in the complex at the N-terminus (residues 7-9) and the C-terminus (residue 134) are small and fall rapidly indicating a higher mobility in these regions as compared to the structured regions of the protein. The relatively ρ_{xy} values observed for residues at the termini - both in the free as well as cytP450-bound cytb₅, - also suggest that the binding of cytb₅ with cytP450 does not significantly change the internal dynamics of cytb₅ residues at the termini. The backbone ρ_{xy} for various residues of cytb₅ in the complex correlate well with that obtained for free cytb₅ (Figure 6), barring few exceptions (e.g., H22-I29, F40, A55-D58 and E74-H85). The residues E74-H85 of cytb₅ are located just before the linker region which undergo fast internal motion in the NMR time scale and could possibly bring a change in dynamics for these residues upon binding to cytP450, which is also consistent with results based on R_2 values. The residue F40 is known to undergo rapid aromatic ring flipping and therefore the observed variation in ρ_{xy} upon complexation with cytP450 could be due to a change in the orientation of its aromatic ring. The residues H22 and K24 are located in the turn region of cytb₅ and are also involved in the cleft opening as proposed by MD simulations.⁷⁶ Thus, these residues may undergo a different time scale of motion upon complex formation that results in the observed deviation. Residues W27-I29 and G56-D58 belong to parallel beta-sheets, 2 and 4, respectively, of cytb₅. It is possible that the tryptophan ring would have experienced an orientational change upon complex formation leading to the observed deviation in ρ_{xy} values for these residues in comparison to that for

free cytb₅. The observed change in ρ_{xy} for these residues of cytb₅ upon complex formation also complement well with the significant variation in R_2 values (Figure 3). In order to understand the overall dynamics in three-dimensional arrangement of cytb₅ in the cytb₅-cytP450 complex with respect to free cytb₅, we have compared the variation of backbone amide-¹⁵N transverse cross-correlated rates (ρ_{xy}) for the structured region such as alpha-helices, beta-sheets and turns. It is evident from the standard deviation of the average ρ_{xy} values that there is only a minor variation in ρ_{xy} values for residues in alpha-helix regions (mean ρ_{xy} value, $18.4 \pm 2.4 \text{ s}^{-1}$ and $15.9 \pm 1.7 \text{ s}^{-1}$ for a bound and free cytb₅, respectively). On the other hand, beta-sheet region (mean ρ_{xy} value, $18.3 \pm 2.8 \text{ s}^{-1}$ and $14.5 \pm 1.1 \text{ s}^{-1}$ for a bound and free cytb₅, respectively) and turns (mean ρ_{xy} value, $17.2 \pm 3.3 \text{ s}^{-1}$ and $14.8 \pm 2.3 \text{ s}^{-1}$ for a bound and free cytb₅, respectively) of cytb₅ in the complex show an increased variation as compared to free cytb₅ (Figure S1 in the Supporting Information) suggesting a larger change in dynamics for beta-sheet and turn residues.

Comparison of backbone amide-¹⁵N CSA for cytb₅ free and in complex with cytP450 determined using transverse cross correlated rates

We have implemented a model independent approach proposed by Fushman and Cowburn to determine ¹⁵N-CSA tensors.⁷⁷ For the calculation of ¹⁵N-CSAs, we have used the ratio; $\rho_{xy}/R_2 = 2d\alpha(P_2(\cos \theta))/(d^2 + c^2)$, under the assumption of axially symmetric CSA tensors.

In the expression, $d = -\mu_0\gamma_N\gamma_H\hbar/4\pi r_{N-H}^3$ represents the dipolar coupling constant with r_{N-H} as the ¹⁵N-¹H bond length and other symbols have their usual meaning. The parameter c represents the CSA constant given by, $c = -\hbar\omega_N(\sigma_{\parallel} - \sigma_{\perp})/3$; where ω_N is the Larmor frequency of ¹⁵N nucleus and $(\sigma_{\parallel} - \sigma_{\perp})$ represents the CSA span (the difference between least shielded ($\sigma_{\parallel}$) and most shielded ($\sigma_{\perp}$) components of CSA tensor). $P_2(\cos \theta)$ is the Legendre polynomial with θ representing the angle between the N-H dipolar vector and the least shielded component in the principal axis system of the ¹⁵N-CSA tensor. As evident from the expression above, the ratio of ρ_{xy} and R_2 depends only on ¹⁵N CSA tensor and ¹⁵N-¹H dipolar coupling; and is independent of contributions from conformational exchange and high-frequency motions provided the rotational diffusion of the macromolecule is isotropic. It is worthwhile to point out that the possibilities of uncertainty in the assumptions used for the determination of amide-¹⁵N CSA will be greater for more mobile regions than for less mobile regions. In the present study, the calculated ρ_{xy} values for various cytb₅ residues in the cytb₅-cytP450 complex show a linear correlation ($R_2 = (0.61 \pm 0.02) \rho_{xy}$) with a uniform spread of data points against R_2 as shown in Figure 7. It can be seen from the plot that ρ_{xy} and R_2 do not correlate well for few residues of cytb₅ in the cytb₅-cytP450 complex. It could be possible that there may be some conformational exchange contributions, between the bound and unbound states of cytb₅ in the cytb₅-cytP450 complex, to transverse relaxation rates leading to the observed variation. This is also validated by a substantial increase in R_2 values for many cytb₅ residues upon binding to cytP450, in comparison to free cytb₅, as shown in Figure 3. Using ρ_{xy} and R_2 values, backbone amide-¹⁵N CSA ($\sigma_{\parallel} - \sigma_{\perp}$) spans for cytb₅ in the cytb₅-cytP450 complex were determined (refer to Table S3 in the Supporting Information for the CSA values) and compared with the values determined for free cytb₅ (Figure 8). The calculations were performed by assuming an effective ¹⁵N-¹H bond length, r_{N-H} , of 1.023 Å and $\theta = 18^\circ$ (the angle between the N-H bond and the least shielded component of ¹⁵N CSA tensor).

Based on the small transverse cross-correlated rate (ρ_{xy}) and transverse relaxation rate (R_2) values observed for the residues K7, D8 and D134 at the termini (Figure 7), these residues were not included in our further analysis as they undergo high-frequency motion (ps-ns rotational correlation time) and, therefore, the experimentally determined CSA tensors for these residues may become time-dependent.^{44,60} We have also omitted a turn residue T13 and a helix residue E43 from our further analysis as they show substantial deviation in the

correlation plot (Figure 7); we believe these residues may undergo a significant conformational exchange as a result the measured CSA values may be inaccurate. The overall mean value of backbone amide- ^{15}N CSA, excluding the outliers at the termini and turns for cytb₅ in the cytb₅-cytP450 complex, was found to be equal to -165.5 ppm which is nearly similar to the mean value of -171.7 ppm obtained for free cytb₅.

Since amide- ^{15}N CSA is extremely sensitive to electrostatic interaction and protein-protein interaction can significantly alter the electronic environment for residues in the interacting interface, significant changes in the CSA span due to cytP450-cytb₅ interaction were observed in this study (Figure 8). Our previous study confirmed that there is no significant change in the secondary structure of cytb₅ upon complex formation with cytP450.⁷² Therefore, the changes in the CSA spans determined for cytb₅ in the cytb₅-cytP450 complex in this study can be attributed to changes in the electronic environment (mainly due to the formation of many transient state encounter complexes) and alteration in the dynamics of cytb₅. Our results show a larger change in the CSA span for residues E49, V50, F63, E64, D65, G67, T70, A72, R73 and E74 that have been found to be in the interacting interface of the cytb₅-cytP450 complex as reported elsewhere.⁷² The fact that the ^{15}N -CSA span for some of these residues (V50, G67, R73 and E74) is reduced and increased for others (E64, D65 and T70) on complexation with cytP450 suggest that a change in the dynamics of cytb₅ alone is unlikely to be a major contributor to the observed changes in the CSA spans. This is further confirmed by the observation that some of the residues (such as E49, F63 and A72) exhibit a smaller change ($<\pm 15$ ppm) in ^{15}N -CSA span as compared to free cytb₅. In addition, one of these residues D65 exhibiting a significant increase in the CSA span in the present study has been found to be involved in the H-bonding interaction and salt bridges formation with R122 and K433 of cytP450.⁷² Our site-directed mutagenesis data also identified less significant role in protein-protein interactions for cytb₅ residues E49 and E42 that also seen to have undergone a smaller change in CSA upon binding to cytP450.

The beta-sheet residues (K10, Y12) and the turn residues (D36, H85) of cytb₅ in the complex show a larger change in ^{15}N CSA span when compared to free cytb₅ even though the ^{15}N transverse cross-correlated rates are nearly similar for these residues in the complex and free cytb₅. The observed large change in ^{15}N CSA for these residues is accounted on the basis of CSA dependence on transverse relaxation rate (R_2) apart from transverse cross-correlated rate (ρ_{xy}), internuclear distance ($r_{\text{N-H}}$) and angle (θ). In the present analysis, amide- ^{15}N CSA could be extracted for only those residues that are independent of exchange contribution and high-frequency (ps-ns timescale) motions as pointed out earlier. Therefore, in the presence of any internal motion both R_2 and ρ_{xy} should be affected equally. However, these residues in the cytb₅-cytP450 complex ($R_2=28.0, 30.2, 31.7$ and 31.4 s⁻¹ for K10, Y12, D36 and H85, respectively; see Table S1 in the Supporting Information for the R_2 values) show a large change in backbone amide- ^{15}N transverse relaxation rates as compared to free cytb₅ ($R_2=19.8, 22.1, 22.7$ and 24.1 s⁻¹ for K10, Y12, D36 and H85, respectively); and as a consequence, we obtained a large change in backbone amide- ^{15}N CSA for these residues. It is interesting to note that phenylalanine residues F40 and F79 of cytb₅, which undergo a small amplitude rapid ring flipping in free cytb₅ (resulting in a small amide- ^{15}N CSA value), become more rigid upon complex formation as indicated by the large change in amide- ^{15}N CSA. On the other hand, W27 that is rigid (high amide- ^{15}N CSA value) in free cytb₅ may seem to undergo certain change in its orientation upon interacting with cytP450 as shown by a reduced amide- ^{15}N CSA value. Residues H22 and K24 belonging to 1- 2 loop of cytb₅ undergo a substantial change in amide- ^{15}N CSA in the cytb₅-cytP450 complex in comparison to free cytb₅. Both these residues are involved in the cleft opening,⁷⁶ on top of cytb₅ and hence are believed to undergo a change in internal dynamics and orientation upon complexation.

Since backbone amide- ^{15}N CSA tensors are sensitive to internal and overall motions of the protein, a difference in the variation of CSA spans for the structured elements such as alpha-helices, beta-sheets and turns may be attributed to the difference in their dynamics in the cytb₅-cytP450 complex as compared to free cytb₅. The mean value for the CSA span was found to be larger in the helical region (−184.5 ppm) than in the beta-sheet (−146.8 ppm) and turns (−146.2 ppm) excluding the outliers in the termini. The higher mean value of ^{15}N CSA span for the helical region in the cytb₅-cytP450 complex, as compared to the overall average of the protein, confirms our earlier results on free cytb₅ (− = −186.2 ppm) that was supposed to be due to an additional contribution from CSA and dipolar shielding anisotropy (DSA) cross-correlated interaction (CSA×DSA).^{78,79} This contribution originates from the interaction of backbone amide protons and nitrogens, that are in close proximity with the thermally averaged electronic spin (Curie spin)^{80,81} of spin ($S=1/2$) paramagnetic center (Fe(III)) of cytb₅, causing a change in the ^{15}N -transverse relaxation rates. The paramagnetic effect was found to be stronger due to an increase in the relaxation rate for amide protons and nitrogens in close proximity to the heme unit.⁸² The mean CSA values of beta-sheet and loop-region residues are found to be smaller in the cytb₅-cytP450 complex as compared to beta sheet (− = −166.0 ppm) and loop region residues (− = −161.1 ppm) in free cytb₅. The decrease in CSA span in these regions of the cytb₅-cytP450 complex could suggest a change in local motion in these regions of cytb₅ when it binds to cytP450 as compared to free cytb₅.

Conclusion

In summary, we have measured ^{15}N CSA/dipolar coupling transverse cross-correlated rates using ^1H -coupled ^{15}N - ^1H HSQC type IPAP spectra to determine ^{15}N CSA tensors for a full-length membrane-bound rabbit cytb₅ in the cytb₅-cytP450B4 complex incorporated in DPC micelles. We have compared the CSA values with our earlier reported values for cytb₅ incorporated in DPC micelles to provide insights into protein-protein interactions.⁵² The measured ^{15}N transverse cross-correlated rates suggest a larger change in dynamics of beta-sheet and turn residues of cytb₅ in the complex as compared to free cytb₅. The overall mean value of amide- ^{15}N CSA, excluding the outliers at termini and turns, for cytb₅ in the cytb₅-cytP450 complex was found to be equal to −165.6 ppm for an NH bond length of 1.023 Å and at $\theta=18^\circ$; this value is similar to the mean value of −171.7 ppm determined for free cytb₅. The observed variation in ^{15}N CSA throughout the amino acid chain of cytb₅ in the cytb₅-cytP450 complex validates the formation of many transient state dynamic encounter complexes formed between the oppositely charged surfaces of cytb₅ and cytP450. The amide- ^{15}N CSA change for various residues located at the interaction interface of cytb₅-cytP450 complex correlates well with the recently reported structure of the complex.^{72,83} The average values of ^{15}N CSA for residues in the helical regions of cytb₅ in the complex was found to be −184.5 ppm, which is consistent with the value reported for free cytb₅. Larger CSA values observed for helical residues of the cytb₅ in the cytb₅-cytP450 complex could possibly be due to the enhanced CSA/DSA cross-correlated rate resulting from the interaction of amide nitrogens and protons with the paramagnetic center Fe(III) of the heme as proposed earlier. We believe that the results presented in this study could pave avenues to utilize CSA tensors in the structural studies of protein-protein and protein-ligand interactions.⁸⁴ In addition, the use of well characterized CSA tensors could be significant in the structural studies of metalloproteins by solid-state NMR spectroscopy.⁸⁵⁻⁸⁷

Figure 1. NMR structure of rabbit microsomal cytb₅ and a cartoon representation of its complex with cytP450

(A) NMR structure of a full-length membrane-bound cytb₅ along with its amino acid sequence. The structure was obtained from a combination of solution and solid-state NMR experiments. The solution NMR method was used to solve the structure of the soluble heme domain (residues 1-104) of full-length cytb₅ incorporated in DPC micelles while the structure of the transmembrane domain (residues 106-126) of full-length cytb₅ incorporated in aligned DMPC/DHPC bicelles was determined using solid-state NMR spectroscopy. (B) A representation of the cytP450-cytb₅ complex illustrating interactions of different domains of cytb₅ with its redox partner cytP450.

Figure 2. TROSY-HSQC spectra of membrane-bound cytb₅ in the presence and the absence of cytP450

(A) 2D ¹⁵N-¹H TROSY-HSQC spectra of a U- ¹⁵N, ¹³C, ²H labeled full-length cytb₅ incorporated in DPC micelles both in free (black) and in complexation with cytP450 (red) along with residue specific resonance assignments. (B) An expansion of the crowded region of the full 2D spectrum (A).

Figure 3. Backbone amide- ^{15}N transverse relaxation rates, R_2 , for cytb_5 residues in DPC micelles

Amide- ^{15}N transverse relaxation rates for cytb_5 alone (red) and in complex with cytP450 (black) are plotted against the residue number.

Figure 4. Representative regions of proton-coupled 2D $^1\text{H}/^{15}\text{N}$ IPAP spectra of a uniformly- ^{15}N , ^{13}C and ^2H -labeled cytb₅ in the cytb₅-P450 complex incorporated in DPC micelles

(A) in-phase (IP) ^{15}N - ^1H doublets, (B) anti-phase (AP) ^{15}N - ^1H doublets, (C) simplified sum (IP - AP) and (D) difference (IP + AP) spectra. The spectra were recorded on a 900 MHz NMR spectrometer using a relaxation delay of 10.64 ms. The transverse magnetization of ^{15}N nuclei was allowed to evolve under ^{15}N chemical shift and ^{15}N - ^1H scalar couplings during the t_1 period of the pulse sequence.

Figure 5. Transverse cross-correlated rates (ρ_{xy}) measurement

The mono-exponential decay curves for the measurement of transverse cross-correlated rates (ρ_{xy}) from the ratio of the up-field and the down-field peak intensities (I_{up}/I_{dn}) for residues T13, T70 and R73 plotted against the relaxation delay time (τ). The corresponding values of ρ_{xy} for these residues are $12.78 \pm 1.12 \text{ s}^{-1}$, $18.35 \pm 1.53 \text{ s}^{-1}$ and $15.79 \pm 2.09 \text{ s}^{-1}$, respectively.

Figure 6. Backbone amide- ^{15}N transverse cross-correlated rates, r_{xy} , for cytb₅ residues
 Backbone amide- ^{15}N transverse cross-correlated rates obtained from mono-exponential decay curves for cytb₅ alone (red) and in complex with cytP450 (black) are plotted against residue number. The transmembrane region of the protein, which could not be observed in solution-NMR due to its dynamics, is represented by a break on the horizontal axis.

Figure 7. A comparison of the backbone amide-¹⁵N transverse cross-correlation rate with the transverse relaxation rate

(A) A comparison between the derived backbone amide-¹⁵N CSA-dipolar cross-correlated rate (η_{xy}) and the transverse relaxation rate (R_2). (B) A linear correlation with a slope= 0.61 ± 0.02 .

Figure 8. Experimentally determined amide- ^{15}N CSA values for cytb₅

Comparison of the variation of amide- ^{15}N CSA for cytb₅ determined from DPC micelle samples containing cytb₅ or cytb₅-cytP450 complex. The ^{15}N CSA ($\sigma_{\parallel}$) tensors of cytb₅ were determined by taking an effective internuclear distance between amide nitrogen and proton atoms ($r_{\text{N-H}}$) as 1.023 Å and a constant value for the angle ($\theta = 18^\circ$) between the amide-N-H bond and the least shielded component of the CSA tensor.
