Abstract

One-pot solvothermal synthesis of a robust tetranuclear sodium hexakis(glycolato)tris(methanolato)aluminate complex Na₃[Al₄(OCH₃)₃(OCH₂CH₂O)₆] via a modified yet rigorous base-catalyzed transesterification mechanism is presented here. Single crystal X-ray diffraction (SCXRD) studies indicate that this unique Al complex contains three penta-coordinate Al³⁺ ions, each bound to two bidentate ethylene glycolate chelators and one monodentate methanolate ligand. The remaining fourth Al³⁺ ion is octahedrally coordinated to one oxygen atom from each of the six surrounding glycolate chelators, effectively stitching the three penta-coordinate Al moieties together into a novel tetranuclear Al complex. This aluminate complex is periodically self-assembled into well-ordered layers normal to the [110] axis with the intra-/inter-layer bindings involving extensive ionic bonds from the three charge-counterbalancing Na⁺ cations rather than the more typical hydrogen bonding interactions as a result of the fewer free hydroxyl groups present in its structure. It can also serve as a valuable precursor toward the facile synthesis of high-surface-area alumina powders using a very efficient rapid pyrolysis technique.

Introduction

Layered materials containing coordinatively unsaturated binding sites such as 5-coordinate Al ([⁵]Al) species are of topical interest because they promise improved performance for lithium-/sodiumion batteries,¹ adsorbent,² and catalyst³ applications. Among these, intercalated layered materials have attracted considerable attention due to their tunable pore size and versatile guest species such as Li⁺ and Na⁺ cations for increased adsorption

capacity and selectivity. They are also important precursors towards preparing nanoscale porous lamellas,⁴ nanotubes,⁵ and composite materials.⁶

Solvothermal synthesis exhibits a significant advantage over conventional hydrothermal technique in cases where either moisture sensitive reagents or potential occurrence of insoluble metal hydroxide side-reactions is inevitably involved in the preparation. Solvothermal synthesis involving polyols (*e.g.*, 1,2-diols) as the solvent has so far been moderately explored for the preparations of novel zeolites,⁷ silicopolyolate containing interesting ^[5]Si species,⁸ and aluminoglycolate analogue containing fascinating ^[5]Al geometry.⁹ For example, Gainsford *et al.* reported a trinuclear $[\text{Al}_3(\text{OCH}_2\text{CH}_2\text{O})_5(\text{OCH}_2\text{CH}_2\text{OH})_2]^{3-}$ anion and several concomitant by-products prepared *via* direct reaction between alumina and NaOH in considerably excessive ethylene glycol (EG) solvent by slowly distilling off both EG and any liberated water from the reaction during the synthesis period until the pseudo-saturation state, followed by a recrystallization step.^{9d}

Although the ^[4]Al and ^[6]Al species in zeolites, clays and minerals, *etc.* have been well studied,¹⁰ relatively few ^[5]Al species have been reported in alkoxide-based crystalline solids to date.^{9,11} Consequently, much less is known about their physicochemical properties, *e.g.*, the chemical-shift “fingerprint” region of ²⁷Al magic angle spinning nuclear magnetic resonance (MAS NMR) spectra for these unique ^[5]Al environments. The study of this unique structure is expected to extend the horizons of such existing systems. We herein report the asymmetric tetranuclear Al complex with three ^[5]Al species, which was achieved by using a modified transesterification synthetic strategy. In addition, we demonstrated the possibilities and benefits of using this layered Al complex as a valuable precursor for efficient preparation of high value-added nanoporous Al₂O₃ powders that are of great relevance both academically and industrially as catalysts, catalyst supports, adsorbents, refractory ceramics, and active feedstocks.

Results and Discussion

We present a novel solvothermal preparative method *via* a modified base-catalyzed transesterification mechanism, which is quite scarcely explored for hybrid inorganic/organic materials preparations,¹² for the synthesis of a layered aluminoalcoholate complex in the presence of methanol as a solvent rather than the more commonly used EG solvent. In the course of the solvothermal reaction, the effective deprotonation from the slightly excessive EG reactant is initially implemented by the action of an aliquot of strong base catalyst of sodium methoxide to initiate the S_N2 nucleophilic substitution reaction, leading to the formation of bidentate ethylene glycolate chelators. These incoming chelators thus formed then compete with three aliquots of sodium methanolate for nucleophilic attack of the Al electrophiles, causing the concurrent departure of CH₃CH₂O⁻ anions (Scheme 1). Due to the chelate nature of the bidentate glycolate ligand, Al electrophiles as ligand acceptors possess a coordinative preference for glycolate ligands over monodentate methanolate ones, thus affording a unique mixed ^[5]Al/^[6]Al complex at a methanolate/glycolate ratio of 1:2 in the final empirical formula. The complexing power with central Al³⁺ cations decreases in the following order: $[\text{OCH}_2\text{CH}_2\text{O}]^{2-} > \text{CH}_3\text{O}^- > \text{CH}_3\text{CH}_2\text{O}^-$. The NaOCH₃ catalyst is

ultimately regenerated by reacting the resultant $\text{NaOCH}_2\text{CH}_3$ with the MeOH formed in the first deprotonation step. It is worth noting that sodium methoxide in slight excess was employed as both the transesterifying base catalyst and one of the reactants. The newly formulated approach is unusual in that only single-step synthesis is utilized without any laborious cycles of fractional-/vacuum-distillations required by previous researchers such as Gainsford *et al.*^{9d} More importantly, this approach is versatile since it only implicates alkali metal alkoxide base-catalyzed alcoholysis but without any intervention of detectable alkaline (OH^-) hydrolysis side-reactions.

In the solvothermal synthesis, the conventional organic transesterification reaction was adapted such that the routine carboxylic acid ester was replaced with pseudo-covalent metal/non-metal alkoxide ester, as exemplified specifically in Scheme 1. This reversible $\text{S}_{\text{N}}2$ nucleophilic substitution reaction involving a competitive ligand-exchange step is expected to be an efficient way to rationally tailor the relative contributions between the nucleation and crystal growth events, thus favoring the efficient large single crystal production. The alcohol-selective rule manifests the possibility of crystal composition tailoring by judiciously choosing different monohydroxy alcohols and polyols. Solvothermal crystallization at 181°C for 5 days resulted in the end product with an actual chemical formula of $\text{Na}_3[\text{Al}_4(\text{OCH}_3)_3(\text{OCH}_2\text{CH}_2\text{O})_6]$. It is anticipated that the coupled high synthetic temperature and high autogenous vapor pressure¹³ applied in the synthesis enable the formation of the largest tetranuclear Al complex of its kind ever reported in the literature. The multi-nuclear nature of this Al complex may explain its insolubility in MeOH , only slight solubility in water and EG, and enhanced stability against both hydrolysis and alcoholysis. This synthetic strategy is universal as long as the large electronegative metal/non-metal (*e.g.*, Si and B) can be prepared in the form of corresponding alkoxides, and is restricted neither by the insolubility of metal oxide/hydroxide in alkaline solutions nor by the potential formation of insoluble metal hydroxide impurities *in-situ* during synthesis, as encountered by other researchers.¹⁴ Moreover, the reactants are not only limited to alkoxide esters, but also include a variety of organic-soluble salts (*e.g.*, chlorides), organometallics and labile metal complexes over the corresponding metalalcoholate ones, although the latter category of reactions cannot be strictly classified as a transesterification reaction.

The details of the crystal structure and its structural refinement are listed in Table 1. The Al compound crystallizes in the monoclinic crystal system and space group $\text{P}2_1/\text{c}$.

As determined by SCXRD, the asymmetric unit (AU) in the crystal structure contains one sodium hexakis(glycolato)tris(methanolato)aluminate complex $\text{Na}_3[\text{Al}_4(\text{OCH}_3)_3(\text{OCH}_2\text{CH}_2\text{O})_6]$ (Fig. 1). Three of the four Al ions reside in considerably distorted $[\text{Al}]$ environments of rectangular pyramidal geometries rather than the more expected trigonal bipyramids by inspecting the O-Al-O bond angles. The remaining fourth Al^{3+} ion in the complex is octahedrally coordinated to one oxygen atom from each of the six glycolate units in the AU, effectively tethering together the three surrounding $[\text{Al}]$ monomers into a tetranuclear configuration (*i.e.*, secondary building unit (BU)) by sharing the basal edges of AlO_5 pentahedra.

The interatomic distances selectively shown in Fig. 1 caption signify a range of Al-O bond strengths for various ligands and Al species. Bonding behaviors in $^{[5]}\text{Al}$ moieties are a contracted Al-O bond to the monodentate methanolate oxygens [Al-O, 1.7539(14)-1.7784(13) Å] compared with bidentate glycolate Al-O bonds [1.7836(14)-1.9122(13) Å]. The shorter Al-O bonds observed for the glycolates invariably involve O atoms with strong Coulombic $\text{Na}^+\text{-O}$ interactions. In contrast, the Al-O bond length in the $^{[6]}\text{Al}$ moiety ranges from 1.8714(13) [Al(1)-O(1)] to 1.9014(13) Å [Al(1)-O(8)]. By comparison, an average Al-O bond length in zeolites is 1.74 Å, which is slightly shorter than the shortest Al-O distance in this aluminohydroxide anion. Additionally, the average O-Al-O bond angle (109.5° in close proximity to the tetrahedral value of 109.4°) in zeolites¹⁵ lies intermediate among all of the O-Al-O bond angles in this Al complex due to the severe structural distortion of the latter Al polyhedra. On the other hand, the Al-O-Al linkage is generally forbidden in aluminosilicate zeolitic frameworks according to the Loewenstein rule¹⁶ obeying Pauling's electrostatic valence principle but with several exceptions for naturally occurring zeolite minerals (*e.g.*, analcime,¹⁷ stilbite¹⁸ and lazurite¹⁹). Zeolites have a representative T-O-T [T (tetrahedral) = Al or Si] bond angle of 141° ¹⁵ which is much larger than Al(1)-O-Al counterparts varying in a much narrower range from $101.24(6)$ to $103.42(6)^\circ$. The magnitude of the Coulombic electrostatic repulsive interaction ($^{[4]}\text{Al}^-\text{-O-}^{[4]}\text{Al}^-$ electrostatic repulsion between Al anions in zeolites vs. $^{[5]}\text{Al}^{0.67-}\text{-O-}^{[6]}\text{Al}^-$ one in the latter) can interpret this big angular difference and what enables the exact existence of Al-O-Al linkages in the Al complex as opposed to synthetic zeolites.

Corroborating the SCXRD studies, the ^{27}Al MAS NMR spectrum (Fig. 2) reveals two highly crystalline Al sites with a 1:3 ratio. The simulated ^{27}Al NMR parameters for Site 1 ($\delta_{\text{iso}} = 6$ ppm and a quadrupolar coupling constant of $C_Q < 2$ MHz) are consistent with the octahedral environment determined by SCXRD. The second site therefore corresponds to the $^{[5]}\text{Al}$ nuclei exhibiting a unique $\delta_{\text{iso}} = 62$ ppm, a moderate $C_Q = 5.5$ MHz and an asymmetry parameter, $\eta = 0.95$. The larger quadrupolar coupling for Site 2 causes a second order broadening which spans 3 kHz at the base. The larger C_Q and η are due to the greater distortion/asymmetry of the $^{[5]}\text{Al}$ sites relative to the $^{[6]}\text{Al}$ one. The unusual chemical shift is observed for the $^{[5]}\text{Al}$ environment as other well-characterized Al-containing oxides are generally located between 20 and 50 ppm.¹⁰ The unique chemical shift is believed to arise from the very unique local structure of the asymmetric unit (Fig. 1) and large Coulombic interactive forces (*vide supra*) whereby one $^{[6]}\text{Al}$ is surrounded by three $^{[5]}\text{Al}$ s creating a localized pseudo-three-fold symmetry. Each $^{[5]}\text{Al}$ species is further capped by two bidentate glycolate ligands causing the shift to a higher frequency. Such a substantial increase in chemical shift is not uncommon as these large shifts have also been observed in a 6-coordinate tris(tropolonato)aluminum(III)²⁰ and 4-coordinate high-alumina cements.²¹

As illustrated in Figs. 1 and S1b, the two glycolate chelators constitute the pyramidal base with a monobasic methanolate occupying the fifth position at the apex, forming the primary BU. The pseudo-pyramidal basal plane is defined *via* the oxygen atoms of the chelating glycolates with the central Al^{3+} ions 0.34-0.38 Å above this rectangular plane. Accordingly, ^{13}C MAS NMR spectra identified two distinct regions representing the various

bidentate glycolate carbons (14 crystallographic carbons) (62–68 ppm) and the methanolate carbons (5 crystallographic carbons) residing at the apex of the rectangular pyramidal $^{[5]}Al$ polyhedral (Fig. 3). The ^{13}C solid-state NMR spectra indicate a highly ordered crystalline structure with ^{13}C line-widths approaching ~ 0.5 ppm (~ 65 Hz). Precise assignment is difficult due to the 19 crystallographic carbons being quite similar in chemical environment. We note however two of the three methanolate carbons were found in a disordered environment (Fig. S1a), hence we speculate these to be assigned to the higher frequency resonance (~ 55 ppm) while the lower frequency resonance (~ 54 ppm) is assigned to the ordered resonance as the area ratio is found close to 2:1. The glycolate carbons represent seven distinct glycolate ligands, five in an ordered arrangement and two in a position-disordered configuration. However, it is interesting that the glycolate region approximately resembles a 1:2:2:1:1 ratio with respect to one another. The absence of J -coupling (*n.a.* ^{13}C , 1.1%) with the combination of MAS and high-power 1H decoupling ($\gamma B_1(^1H) = 100$ kHz) removes the remaining chemical shielding and dipolar anisotropies, leaving behind pure isotropic chemical shift information. Without further symmetry constraints available, the exact assignment is not currently attainable.

The assembly process of the crystal structure of the aluminate complex from a 1D chain to a 2D plane and to a 3D architecture is sequentially illustrated in Fig. 4. Fig. 4a shows the 1D chain building block comprising 3 AUs that are held together by two coordinatively saturated 6-coordinate Na^+ cations with respect to Oxygens, forming the in-plane Na-O ionic bonds. To completely establish the coordinatively saturated structure, a fraction of under-coordinated 2-coordinate Na^+ species on each AU functions as cross-linker to bind the adjacent chains together by out-of-plane Na-O ionic interactions into one 2D layer parallel to (110) crystal plane (Fig. 4b). As shown in Figs. 4c and S2 both highlighting a layered structure, the 3D structure viewed along the crystallographic $[110]$ axis is constructed by periodically stacking two (110) planes layer-by-layer with the interlayers cross-linked by the out-of-plane coordinatively unsaturated Na-O ionic bonds remaining on the (110) planes. Likewise, the $(\bar{1}10)$ -parallel interlayers are also bound together by different out-of-plane Na^+ cations (Fig. 4c).

The experimental PXRD pattern of this sample closely matches the simulated XRD pattern derived from the SCXRD structure, suggesting the high phase purity of our powdered sample (Fig. 5). The experimental PXRD pattern exhibits a predominantly intense (110) reflection at $10.5^\circ 2\theta$ ($8.42 \text{ \AA}$ in (110) interplanar d -spacing) without any noticeable background intensity, characteristic of a (110)-dominant and well-crystallized Al complex. The typical (110) basal series peak until (220) manifests a material of a well-organized layered structure. As indicated in Figs. S2 and S3, the orientation of the chosen parallel layers is consistent with the PXRD-characterized result. It is worth noting here that we select (110) as the basal plane of these layers instead of $(\bar{1}10)$. Also, the interlayer spacing of this material could be finely tuned either by delamination or by substituting out-of-plane Na^+ cations through post ion-exchange or direct synthetic means, thus making it a potential adsorbent.

The thermal stability of the Al complex was evaluated by TGA operating in both flowing N_2 and air streams, as shown in Fig. 6. Under flowing N_2 atmosphere, between 25 and $350^\circ C$,

there exhibited *ca.* 2.3% weight loss likely corresponding to the evaporation of physisorbed water, occluded MeOH solvent, and/or loosely bound methanolate-like ligands. With increasing temperature, two distinguishable weight losses were observed before the final plateau based on the DTG profile. The first very small weight loss centered at *ca.* 380 °C (~1.2%) is likely due to the loss of a small portion of relatively strongly bound methanolate-like ligands. A dramatic weight loss associated with the framework collapse was then observed between 405 and 550 °C with a temperature inflection point at 438 °C. In contrast, under flowing air, the onset degradation temperature occurred at 300 °C, and an overall weight loss of 52.9% was observed, ultimately leading to the whitened decomposition powders. The theoretical weight loss for the conversion from $C_{15}H_{33}Al_4Na_3O_{15}0.1CH_4O$ to a stoichiometric oxide $3NaAlO_20.5Al_2O_3$ is 53.1%, which agrees well with the total weight loss occurring in the air stream, but differs from that of 46.2% in the N_2 stream. The reason for this discrepancy is the concomitant formation of minor carbon residues (~6.5%) in the anaerobic conditions, as indicated by the blackened appearance of the end powders. As such, this layered material is quite thermally stable under N_2 or air atmosphere. On the other hand, part of the in-plane Na^+ counterions and framework Al^{3+} ions are roughly sandwiched by alkoxides (Fig. 4c), thereby inhibiting to some extent the hydrolysis of Al^{3+} ions upon contact with moisture in favor of its hydrolytic stability accordingly.

Fig. 7 showed the ATR-FTIR spectrum of the Al complex. A very weak broad O-H band in the region of $3500-3200\text{ cm}^{-1}$ is marginally visible, indicating very low content of free alcohol or non-fully-condensed hydroxyl residues present in the crystals, and consequently very weak hydrogen bonding interaction arises. This result is in good agreement with the SCXRD and TGA analyses. The strong band at $2950-2850\text{ cm}^{-1}$ is due to the alkyl C-H stretching vibrations. By analogy with zeolites, the vibrational frequencies of the zeolite lattice, which result from the stretching and bending modes of the T-O units, are observed in the range between 200 and 1500 cm^{-1} .²² Since the average Al-O bond length in zeolites is shorter than those in the current Al complex (*vide supra*), the Al-O vibrational frequencies in the former shift to slightly higher wavenumbers than the latter. Hence, we attribute the absorption band at $500-1460\text{ cm}^{-1}$ to the Al-O vibrational frequencies of the Al complex. Obviously, no free hydroxyl groups present in its empirical formula other than those from the occluded MeOH solvent (*ca.* 10% occupancy, *cf.* Fig. S1a) account for the fewer hydrogen bonding interactions in the crystal lattice, as confirmed by ATR-FTIR. Therefore, it justifies the effectiveness of the sodium methoxide catalyst in full condensation.

In addition, the preliminary findings suggest that this Al complex is a useful precursor towards the facile preparation of high-surface-area alumina powders by a fast pyrolysis technique ($10\text{ }^\circ\text{C/min}$), giving hierarchically porous alumina grains. Figs. 8 and 9 show the N_2 sorption isotherms, and PSD and cumulative pore volume of the pyrolyzed Al complex precursor without any aqueous leaching, respectively. It is found that the S_{BET} is up to $91.7\text{ m}^2/\text{g}$ together with the V_t of 0.103 ml/g for pores smaller than 41.8 nm (width) at an RP of 0.95. After experiencing aqueous leaching of $NaAlO_2$ component, the S_{BET} of the resulting alumina powders is slightly enhanced to $104.9\text{ m}^2/\text{g}$ with the corresponding V_t nearly unchanged (not shown here). Moreover, the V_{meso} of the unwashed sample dominates the

total pore volume accounting for 86.4%. As shown in Fig. 9, the mesopore radius at the maximal PSD is 19.15 Å.

Conclusions

In summary, a new well-crystallized and phase-pure tetranuclear Al complex was successfully synthesized by utilizing a modified transesterification reaction. Its layered crystal architecture comprising a network of the combination of $^{[5]}Al$ and $^{[6]}Al$ geometries was determined via SCXRD analysis and further corroborated via ^{27}Al and ^{13}C MAS NMR spectroscopies. Another feature lies in that the Al-O-Al linkage is allowed in its crystal structure as a result of slightly weakened electrostatic repulsive interactions between Al centers as compared with synthetic zeolites. The coordinatively unsaturated Al binding sites within the porous lattice and high thermal stability could be an attractive property for the potential applications of this material as an adsorbent. In addition, the versatile synthetic methodology proposed in this study is expected to open up a new avenue to elegantly design new porous metal-organic materials. Finally, this study provides a new route for the efficient fabrication of highly nanoporous alumina powders with hierarchical micro-/meso-porosity.

Experimental Section

1. Solvothermal synthesis

A transesterification synthetic strategy was formulated to prepare this layered Al complex $Na_3[Al_4(OCH_3)_3(OCH_2CH_2O)_6]$. No special care was taken to exclude the exposure to extraneous moisture, and all manipulations were carried out in a well-ventilated fume hood. All chemicals were purchased from Sigma-Aldrich and used as received.

A recipe of $Al(OC_2H_5)_3$: 3EG: $NaOCH_3$: $15CH_3OH$ on a molar basis was originally developed. In the synthesis, 2.93 g of sodium methoxide powders (97%) were completely dissolved in 23.57 g of anhydrous methanol solvent (99.8%) under stirring before the addition of 8.79 g of aluminium ethoxide powders (97%). When the dissolution of the Al source was complete, 9.90 g of EG was rapidly added dropwise under intense agitation. The aging was maintained overnight at room temperature (RT) under stirring in a tightly sealed autoclave to ensure adequate homogenization. The solvothermal synthesis was then statically carried out at 181 °C under autogenous pressure for 5 d. The solid fraction was recovered *via* vacuum suction filtration and successively rinsed with anhydrous methanol, anhydrous tetrahydrofuran (THF, 99.9%), and further anhydrous methanol. The collected solid was vacuum dried at 80 °C for 10 h yielding 3.5 g of dry powders which were stored in a desiccator for future structural characterization. The colourless crystalline product appeared as polycrystalline powders with a few sparse X-ray-quality single crystals (e.g., $0.11 \times 0.04 \times 0.01$ mm³ in dimension). It is worth noting that the above synthetic protocol was not optimized as the approach proposed here is robust and readily reproducible.

2. Pyrolytic preparation of porous alumina powders

To achieve porous alumina composite for N₂ sorption measurement, fast pyrolysis was conducted on the Al complex precursor (several tens of mg) in a flowing air atmosphere (~25 ml/min) in a TGA furnace using a ramping rate of 10 °C/min up to 900 °C and a

soaking duration of 3 min. Part of the pyrolyzed white powders were subsequently subjected to adequate aqueous rinse overnight at room temperature under stirring to yield pure alumina product.

3. Single-crystal X-ray diffraction (SCXRD)

Low-temperature ($-173\text{ }^{\circ}\text{C}$) XRD data comprising φ - and ω -scans were collected using a Bruker-AXS X8 Kappa Duo diffractometer coupled with a Smart Apex II CCD detector with an $I\mu\text{S}$ source of Mo K_{α} radiation ($\lambda = 0.71073\text{ \AA}$). The structure was solved by direct methods using SHELXS²³ and refined against F^2 on all data by full-matrix least squares with SHELXL-97²⁴ using established refinement strategies.²⁵ All non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were calculated geometrically and refined using a riding model. The isotropic displacement parameters of all hydrogen atoms were fixed to be 1.2 times the U_{eq} value of the atom to which they are bound (1.5 for methyl groups). The representations of the positional disorders of some atoms and the asymmetric unit of the title crystal showing the empirical formula $\text{C}_{15}\text{H}_{33}\text{Al}_4\text{Na}_3\text{O}_{15}0.1\text{CH}_4\text{O}$ involving $\sim 10\%$ occupancy of MeOH solvent molecule were illustrated in Fig. S1a.

4. Solid-state NMR (ssNMR)

Solid-state NMR experiments were performed at either 11.7 (500 MHz, ^1H) or 16.4 T (697 MHz, ^1H) using a home-built NMR spectrometer (courtesy of Dr. D. Ruben, FBML-MIT) and a 3.2 mm Chemagnetics triple-resonance MAS probe for ^{13}C and ^{27}Al , respectively. The crystalline sample was ground using an agate mortar and pestle under dry atmosphere and packed quickly into a 3.2 mm (o.d.) ZrO_2 rotor ($\sim 26\text{ }\mu\text{l}$ sample). ^{27}Al spectra were acquired at a spinning frequency, $\omega_r = 16000(4)\text{ Hz}$ and between 4096 and 65536 co-added transients. Recycle delays were optimized using a saturation recovery experiment and set to 1.2 s using a Bloch²⁶ experiment with a short quantitative tip angle (14°) and 3.0 s using a Hahn echo²⁷ sequence ($^{27}\text{Al } \gamma B_1 = 60\text{ kHz}$). Non-spinning experiments (not shown here) were also collected using identical parameters above (Hahn-echo) with 83 kHz of ^1H continuous-wave decoupling. ^{27}Al spectra were referenced relative to 1.1 M $\text{Al}(\text{NO}_3)_3$ solution at 0 ppm.²⁸ $^{13}\text{C}\{^1\text{H}\}$ CP²⁹ and direct detection spectra were acquired at $\omega_r = 13450(1)\text{ Hz}$, 8192 co-added transients and recycle delay of 3 and 25 s, respectively. The contact time during the CP experiment was set to 1.5 ms. Both experiments were acquired using high-power ($^1\text{H } \gamma B_1 = 100\text{ kHz}$) two-pulse phase modulation (TPPM)³⁰ ^1H decoupling during acquisition. ^{13}C spectra were referenced using solid adamantane to 40.49 ppm.³¹ The magic angle within the probe was set using the ^{79}Br resonance of solid KBr and shimmed using adamantane prior to signal acquisition. The sample temperature was regulated between 22 and 26 $^{\circ}\text{C}$ during acquisition. All spectra were processed using RNMTP data processing software; quadrupolar line shapes were simulated using either WSOLIDS or SPINEVOLUTION software packages.³²

5. Powder X-ray diffraction (PXRD)

PXRD pattern was taken using a PANalytical X'Pert Pro Multipurpose Diffractometer in reflectance Bragg-Brentano geometry at 45 kV and 40 mA using Ni-filtered Cu K_{α} radiation

($\lambda = 1.54 \text{ \AA}$). The data collection was carried out at a constant temperature of 25°C with a step increment of $0.084^\circ 2\theta$, a counting time of 6.4 s/step, and the 2θ angular range from 3 to 50° .

6. Thermogravimetric analysis (TGA)

The sample with an initial mass of 18.48 mg was heated in a Pt pyrolytic pan at a constant ramping rate of $10^\circ\text{C}/\text{min}$ from ambient temperature up to 800°C on a Discovery TG analyzer (TA Instruments) in flowing N_2 and air atmospheres both set to $25 \text{ ml}/\text{min}$. The isothermal duration at 800°C was set to 3 min.

7. Attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR)

IR absorbance spectrum was collected on the Al complex using a Nexus 870 FT-IR E.S.P. spectrometer (Thermo Scientific) equipped with an ATR accessory with a single reflection diamond crystal. The FT-IR chamber was flushed constantly with flowing N_2 stream (*ca.* $0.71 \text{ m}^3/\text{h}$). Scans at a spectral resolution of $\pm 4 \text{ cm}^{-1}$ were taken at RT on a self-supporting sample disc from 4000 to 500 cm^{-1} . Sixteen scans were averaged, and the resulting spectrum was background subtracted.

8. Gas sorption analysis on the pyrolyzed Al complexes with and without aqueous rinse

Gas sorption studies were carried out to investigate the textural properties of the pyrolyzed products ($3\text{NaAlO}_2 \cdot 0.5\text{Al}_2\text{O}_3$) with and without aqueous rinse. The N_2 sorption measurement was performed at -196°C using an Autosorb iQ2 automated gas sorption analyzer (Quantachrome). Before adsorption run, the sample was degassed under vacuum (*ca.* 0.2 Pa) at 370°C for 12 h. Afterwards, a proper glass rod filler was inserted in a sample cell to minimize the cell dead voids. The BET (Brunauer, Emmett, and Teller) surface area (S_{BET}) was obtained by applying the BET equation to a relative pressure (RP) range of 0.05 - 0.30 on the adsorption branch. The total pore volume (V_t) was evaluated from the adsorbed N_2 amount at a maximum RP of 0.95 . The pore size distribution (PSD) was calculated by the BJH (Barrett, Joyner, and Halenda) method on the desorption branch. The micropore volume (V_{micro}) was determined by applying the D-R (Dubinin-Radushkevich) equation to an RP range of 0.00005 - 0.009 on the adsorption isotherm.

Fig. 1.

Asymmetric-unit structure of the aluminate complex $\text{Na}_3[\text{Al}_4(\text{OCH})_3(\text{OCH}_2\text{CH}_2\text{O})_6]$ comprising three $^{[5]}\text{Al}$ moieties stitched together by a fourth $^{[6]}\text{Al}$. Hydrogen atoms are omitted for clarity, and thermal ellipsoids are set to 50% probability. Selected interatomic bond distances ($\text{\AA}$) and bond angles ($^\circ$): Al(2)-O(13): 1.7539(14), Al(3)-O(14): 1.7784(13), Al(4)-O(15): 1.7661(14), Al(4)-O(11): 1.7836(14), Al(4)-O(12): 1.9122(13), Al(1)-O(1): 1.8714(13), and Al(1)-O(8): 1.9014(13); Al(1)-O(12)-Al(4): 101.24(6), and Al(1)-O(9)-Al(4): 103.42(6).

Fig. 2.

^{27}Al MAS NMR spectrum acquired at 16.4 T (experimental) and corresponding simulation of two distinct aluminium coordination environments, *i.e.*, 5-coordinate (^{15}Al) and 6-coordinate (^{16}Al).

Fig. 3.

^{13}C MAS NMR spectrum of the Al complex acquired using $^{13}\text{C}\{^1\text{H}\}$ cross-polarization (CP) at 11.7 T (a). Inset represents a magnified region (50-70 ppm) with the glycolate and methanolate ligands identified using CP (b) and direct (Bloch) detection (c) over 8 and 60 h, respectively.

Fig. 4.

Flowchart of the assembly process of the crystal structure from a 1D chain along c axis (**a**), to a 2D viewed parallel to (110) plane (**b**), and to a 3D viewed along the $[110]$ axis highlighting the layered structure (**c**). Hydrogen atoms are omitted for clarity.

Blue: Al; red: O; gray: C; and yellow: Na.

Fig. 5.

Top: Simulated PXRD pattern of as-synthesized layered sodium aluminosilicate single crystal, and Bottom: Experimental PXRD pattern of the same powders. Well-ordered and typical 110 basal series peaks from (110) to (220) in both patterns.

Fig. 6.

TGA profiles of the Al complex in flowing N₂ (black curve) and air streams (blue curve). The red curve represents the DTG (derivative thermogravimetry) for the black trace.

Fig. 7.

ATR-FTIR spectrum of the Al complex recorded under ambient condition.

Fig. 8.

N₂ adsorption/desorption isotherms of the pyrolyzed Al complex without any aqueous rinse post treatment.

Fig. 9.

PSD and cumulative pore volume of the pyrolyzed Al complex without any aqueous rinse post treatment.

Scheme 1.

Proposed reaction pathway to the target product $\text{Na}_3[\text{Al}_4(\text{OCH}_3)_3(\text{OCH}_2\text{CH}_2\text{O})_6]$ starting with aluminium alkoxide, EG and sodium methoxide by a modified transesterification mechanism.

Table 1

Crystallographic data and structural refinement for the Al complex.

Parameter	Data
CCDC No.	955650
Empirical formula	$C_{15}H_{33}Al_4Na_3O_{15} \cdot 0.1CH_4O$
F.W.	633.35
Temp.	100(2) K
Wavelength	0.71073 Å
Crystal system	monoclinic
Space group	$P2_1/c$
	$a = 11.2481(12)$ Å; $\alpha = 90^\circ$
Unit cell dimensions	$b = 13.1877(14)$ Å; $\beta = 105.738(2)^\circ$
	$c = 18.235(2)$ Å; $\gamma = 90^\circ$
Volume	$2603.5(5)$ Å ³
Z	4
Density (calculated)	1.616 mg/m ³
Absorption coefficient	0.299 mm ⁻¹
$F(000)$	1319
Crystal size	$0.11 \times 0.04 \times 0.01$ mm ³
θ collection range	1.88 to 30.99° .
Index ranges	$-16 \leq h \leq 15$, $-19 \leq k \leq 18$, $-26 \leq l \leq 26$
Reflections collected	67765
Independent reflections	8270 [$R_{int} = 0.0539$]
Completeness to $\theta = 30.99^\circ$	99.7%
Absorption correction	Semi-empirical from equivalents
Max. and min. transmission	0.9970 and 0.9678
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	8270/459/395
Goodness-of-fit on F^2	1.046
Final R indices [$I > 2\sigma(I)$]	$R1 = 0.0405$, $wR2 = 0.0994$
R indices (all data)	$R1 = 0.0633$, $wR2 = 0.1110$
Largest diff. peak and hole	0.521 and -0.438 e.Å ⁻³
