Abstract

Peroxisome proliferator-activated receptor α (PPAR α) is an important regulator of hepatic lipid metabolism which functions through ligand binding. Despite high amino acid sequence identity (>90%), marked differences in PPAR α ligand binding, activation and gene regulation have been noted across species. Similar to previous observations with synthetic agonists, we have recently reported differences in ligand affinities and extent of activation between human PPAR α (hPPAR α) and mouse PPAR α (mPPAR α) in response to long chain fatty acids (LCFA). The present study was aimed to determine if structural alterations could account for these differences. The binding of PPAR α to LCFA was examined through *in silico* molecular modeling and docking simulations. Modeling suggested that variances at amino acid position 272 are likely to be responsible for differences in saturated LCFA binding to hPPAR α and mPPAR α . To confirm these results experimentally, LCFA binding, circular dichroism, and transactivation studies were performed using a F272I mutant form of mPPAR α . Experimental data correlated with *in silico* docking simulations, further confirming the importance of amino acid 272 in LCFA binding. Although the driving force for evolution of species differences at this position are yet unidentified, this study enhances our understanding of ligand-induced regulation by PPAR α and demonstrates the efficacy of molecular modeling and docking simulations.

Introduction

Peroxisome proliferator-activated receptor alpha (PPAR α) belongs to the nuclear hormone receptor superfamily of ligand-dependent transcription factors and has emerged as one of the central regulators of nutrient-gene interactions. Structurally similar to other members of the nuclear hormone receptor family, the PPAR α protein structure consists of an N-terminal ligand-independent transactivation function (AF-1), a highly conserved DNA binding domain (DBD), a hinge region and the C-terminal ligand binding domain (LBD) containing a ligand-dependent transactivation function (AF-2). The LBD of PPAR α constitutes a large hydrophobic ligand-binding pocket (1300–1400 Å³) that allows interaction with a broad range of natural and synthetic ligands [1, 2]. PPAR α interacts with a variety of endogenous ligands, including fatty acids and fatty acid metabolites, as well as synthetic compounds such as hypolipidemic fibrate drugs, to regulate cellular processes related to fatty acid metabolism, glucose metabolism, inflammation, differentiation and proliferation [3–6].

While long-chain fatty acids (LCFA) serve as major metabolic fuels and important components of biological membranes, they also play a significant role as signaling molecules and gene regulators in response to food intake and nutritional changes. Recently, we have demonstrated that LCFA and their thioesters (long-chain fatty acyl-CoA; LCFA-CoA) constitute high-affinity endogenous ligands of human PPAR α (hPPAR α) and mouse PPAR α (mPPAR α). Such ligand binding induces PPAR α conformational changes and increases transactivation, consistent with expectations for an endogenous ligand of a ligand-activated nuclear receptor [7]. Thus, PPAR α in conjunction with LCFA and their metabolites could serve to regulate metabolic pathways governing fuel utilization, storage, transport and mobilization. However, we also reported differences in binding affinities and the extent of ligand-induced transactivation between mPPAR α and hPPAR α in response to saturated LCFA [7].

Species differences in PPAR α -mediated downstream regulation of target genes have been noted previously [8, 9]. Human and mouse PPAR α proteins promote transcription to a different extent in response to certain hypolipidemic agents and phthalate monoesters [10, 11]. Furthermore, it is well established that long-term administration of PPAR α agonists result in hepatic cancer in rats and mice – an effect that does not occur in guinea pigs, canines, non-human primates, or even humans [12]. While a single cause for the existence of such differences is highly unlikely, possible explanations include: differences in expression levels of PPAR α or differences in PPAR α target genes, alternatively spliced or mutant forms of PPAR α protein, mutations or polymorphisms in target gene response elements, increased expression of oncogenes and/or inhibition of apoptosis [12–15]. However, transgenic mice that express human PPAR α mainly in the liver do not exhibit hepatocarcinogenesis upon administration of PPAR α agonists [16, 17]. This observation suggests that structural differences in the PPAR α protein could be the underlying cause of such species variation.

Comparison of the PPAR α amino acid sequence across species, particularly of the LBD, resulted in >90% homology [18]. However it should be noted that a single amino acid change can result in marked alterations in ligand selectivity of nuclear receptors. For

example, a single amino acid change in the mouse PPAR α -LBD (E282) results in altered activity of the protein [19], and a valine to methionine substitution in human PPAR α (V444M) produced PPAR δ ligand binding characteristics, resulting in loss of fibrates responsiveness [20]. While we have reported differences in mPPAR α and hPPAR α in response to saturated LCFA [7], the goal of this study was to explore the mechanisms underlying such divergence. We have used methods including: molecular modeling and *in silico* docking, mutagenesis, spectrofluorometry, circular dichroism spectroscopy and transactivation studies to identify a single amino acid change at position 272 that is largely responsible for the altered saturated LCFA binding.

Material and Methods

Molecular modeling simulations

The crystal structure of the ligand binding domain (LBD) of hPPAR α complexed with a synthetic agonist (GW409544) was retrieved from RCSB Protein Data Bank (PDB identifier 1K7L) [2]. This structure was chosen due to the completeness of the crystal structure (no missing amino acid side chains). The apo form of hPPAR α -LBD was generated by extracting the ligand (GW409544) from the 1K7L model (using Swiss PDB Viewer, <http://www.expasy.org/spdbv/>). This structural model was used in all docking simulations. Since the structure of mPPAR α has not been crystallized, a homology modeling approach was used to generate the mPPAR α -LBD structure. We compared the amino acid sequence of hPPAR α to mPPAR α and substituted all amino acid residues that were different in the hPPAR-LBD crystal structure. In total, 23 amino acid residues in the hPPAR α -LBD were replaced with the corresponding mPPAR α residues, followed by energy minimization of the resulting model. This model was used as an initial structure of mPPAR α -LBD for all docking simulations. All energy computations were done in vacuo using GROMOS96 43B1 parameters without reaction field, implemented in Swiss PDB Viewer [21]. An energy minimized model of the F272I mPPAR α -LBD was also generated using the Swiss PDB Viewer (<http://www.expasy.org/spdbv/>).

Molecular docking simulations

In silico docking studies were performed using both AutoDock Vina 1.1.2 [22] and the FlexiDock^{TM} module available on SYBYL®-X 2.0 (Tripos, St. Louis, MO). While AutoDock Vina 1.1.2 allows only the ligand to have flexible/rotatable bonds, the FlexiDock^{TM} module on SYBYL®-X 2.0 permits both protein (sidechains) and ligands to carry flexible/rotatable bonds. For docking with both AutoDock Vina 1.1.2 and FlexiDock^{TM}, a search space or putative binding site was defined in a restricted region of the protein. In the present study, the ligand binding pocket was defined based on the experimentally obtained structure of the GW409544 ligand bound to hPPAR α -LBD [2]. Once the hPPAR α and mPPAR α models were energy minimized, docking simulations were conducted using both AutoDock Vina 1.1.2 and FlexiDock^{TM}. Docking simulations were first validated using the GW409544 ligand by comparing the X-ray crystal structure 1K7L (hPPAR α -LBD + GW409544) with that of the docking output generated for apo-hPPAR α with GW409544. Both AutoDock Vina 1.1.2 and FlexiDock^{TM} generated multiple docking poses (differentiated by RMSD

relative to the best pose) that were subjected to careful visualization, and only the most energetically favorable conformations were chosen for further analysis.

Docking of LCFA was carried out using both AutoDock Vina 1.1.2 and FlexiDock™. For each binding conformation, the binding energies were calculated using the FlexiDock scoring function based on the Tripos Force Field, as implemented by FlexiDock. The resulting docking conformations were visualized using the PyMOL Molecular Graphics System (Version 1.5.0.4 Schrödinger, LLC) and the program LIGPLOT [23]. In order to determine the volume of each ligand binding pocket, the PVOME algorithm was utilized [24]. Based on the occupancy of GW409544 within the hPPAR α ligand binding pocket, the ligand binding pocket was defined using 37 overlapping inclusion spheres. This pocket was visualized using the Visual Molecular Dynamics (VMD) program [25], and volume-grid points near the protein atoms were systematically deleted with a padding variable of 1.09 (radius of a hydrogen atom) or 0.5 (half of a carbon-hydrogen bond length) using POVME [24]. This was followed by volume measurement of the resultant binding pocket. This process was then repeated for mPPAR α and F272I mPPAR α .

Chemicals

Fluorescent fatty acid (BODIPY-C16) was purchased from Molecular Probes, Inc. (Eugene, OR). Docosahexaenoyl-CoA and BODIPY C16-CoA were synthesized and purified by HPLC as previously described [26] and found to be >99% unhydrolyzed. Rosiglitazone was generously provided by Dr. Khalid Elased (Wright State University). All other putative ligands were from Sigma-Aldrich (St. Louis, MO).

Purification of Recombinant F272I mutant mPPAR α protein

The cloning and purification of wild-type 6xHis-GST-mPPAR α has been described [7]. A mutant form of full-length mPPAR α (amino acids 1–468) in which the phenylalanine residue at 272 in helix 3 was replaced by isoleucine (F272I; to mimic hPPAR α) was used for all experiments presented herein. The F272I mutation was generated by overlap PCR of 6xHis-GST-mPPAR α using the following primers: 5' – AAGAGAATCCACGAAGCCTA – 3', 5' – GAAGACAAAGAGGCAGAGGTCCGAATCTT – 3', 5' – GGACATGCACTGGCAGTGGGAAGATTCG – 3' and 5' – CCGGGAGCTGCATGTGTCAGAGG – 3'. The PCR product contained internal *Sma* I and *Xho* I sites which were used to replace the 3' half of wild-type mPPAR α in the 6xHis-GST-mPPAR α vector with the mutated PCR fragment to produce 6xHis-GST-F272ImPPAR α . This plasmid was confirmed by sequencing. The full-length recombinant mutant F272I mPPAR α protein was expressed in Rosetta™2 cells (Novagen, Gibbstown, NJ) and purified as described previously for the wild-type [7]. The protein purity was verified using SDS-PAGE with Coomassie blue staining and immunoblotting. Protein concentrations were estimated by Bradford Assay (Bio-Rad Laboratories, Hercules, CA) and by absorbance spectroscopy using the molar extinction coefficient for the protein.

Fluorescence based Ligand Binding Assays

The binding affinity of F272I mPPAR α to a fluorescent 16 carbon fatty acid analogue (BODIPY C16) or its CoA thioester (BODIPY C16-CoA) was determined as described

previously for wild-type mPPAR α [7]. Based on the binding affinities obtained herein, displacement assays were performed in the presence of BODIPY C16-CoA (110 nM) using non-fluorescent LCFA and LCFA-CoA as described previously [7]. The maximal fluorescence intensity was measured, and the effect of increasing concentrations of naturally-occurring non-fluorescent ligands was measured as a decrease in fluorescence. The direct binding of F272I mPPAR α to non-fluorescent ligands was also determined by quenching of intrinsic PPAR α aromatic amino acid fluorescence as described previously for wild-type mPPAR α [7, 26]. For all measurements, emission spectra were corrected for background and inner-filter effects were avoided. Changes in fluorescence intensity were used to calculate the dissociation constant (K_d), inhibition constant (K_i) and the number of binding sites (n) as described previously [27].

Circular Dichroism

Circular dichroic spectra of F272I mPPAR α (0.6 μ M in 600 μ M HEPES pH 8.0, 24 μ M dithiothreitol, 6 μ M EDTA, 6mM KCl and 0.6 % glycerol) were recorded in the presence and absence of LCFA and LCFA-CoA (0.6 μ M) with a J-815 spectropolarimeter (Jasco Inc., Easton, MD) as previously described for the wild-type mPPAR α [7]. Spectra were recorded from 260 to 187 nm with a bandwidth of 2.0 nm, sensitivity of 10 millidegrees, scan rate of 50 nm/min and a time constant of 1 s. Ten scans per replicate were averaged, and the average spectrum was used to determine the percent composition of α -helices, β -strands, turns and unordered structures with the CONTIN/LL program of the software package CDpro[27, 28].

Mammalian Expression Plasmids

The pSG5-hPPAR α , pSG5mPPAR α , pSG5-hRXR α and pSG5-mRXR α plasmids have been described [7]. The F272I mutant mPPAR α was amplified from 6xhis-GST-F272I mPPAR α using the following primers: 5'-cggatccaccATGGTGGACACAGAGAGCCCC-3' and ctctcgcagTCAGTACATGTCTCTGTAGA-3'. In these primers, lowercase represents nucleotides outside of the PPAR α open reading frame and restriction sites are underlined. The PCR product was cloned into the pGEM®-T easy vector (Promega Corp., Madison, WI). A *Bam* HI/end-filled *Xho* I F272I mutant mPPAR α fragment was subcloned into the *Bam* HI/end-filled *Bgl* II multiple cloning site of pSG5 (Stratagene, La Jolla, CA) to produce pSG5-F272I mPPAR α . The reporter construct, PPRE $\times$ 3 TK LUC was a kind gift of Dr. Bruce Spiegelman (Addgene plasmid # 1015) and contained three copies of the acyl-CoA oxidase (ACOX) peroxisome proliferator response element (PPRE) [29].

Cell culture and Transactivation assay

COS-7 cells (ATCC, Manassas, VA) were grown in DMEM supplemented with 10 % fetal bovine serum (Invitrogen, Grand Island, NY), at 37°C with 5% CO₂ in a humidified chamber. Cells were seeded onto 24-well culture plates and transfected with Lipofectamine™ 2000 (Invitrogen, Grand Island, NY) and 0.4 μ g of each full-length mammalian expression vector (pSG5-hPPAR α and pSG5-hRXR α , pSG5-mPPAR α and pSG5-mRXR α , pSG5- F272I mPPAR α and pSG5-mRXR α .) or empty plasmid (pSG5), 0.4 μ g of the PPRE $\times$ 3 TK LUC reporter construct, and 0.04 μ g of the internal transfection

control plasmid pRL-CMV (Promega Corp., Madison, WI) as previously described [27]. Following transfection incubation, medium was replaced with serum-free medium for 2 h, ligands (1 μ M) were added, and the cells were grown for an additional 20 h. Fatty acids were added as a complex with bovine serum albumin (BSA) as described [27, 30]. Firefly luciferase activity, normalized to *Renilla* luciferase (for transfection efficiency), was determined with the dual luciferase reporter assays system (Promega Corp., Madison, WI) and measured with a SAFIRE² microtiter plate reader (Tecan Systems, Inc. San Jose, CA). The clofibrate treated samples in each case, overexpressing both PPAR α and RXR α , were arbitrarily set to 1.

Statistical Analysis

Data were analyzed using a one-way ANOVA to evaluate overall significance (SigmaPlot^{TM}, Systat Software, San Jose, CA). A Fisher Least Significant Difference (LSD) post-hoc test was used to identify individual group differences. The results are presented as mean $\pm$ SEM. The confidence limit of $p < 0.05$ was considered statistically significant.

Results and Discussion

Since its discovery and cloning, PPAR α has been shown to be activated by structurally diverse ligands, including the fibrate class of drugs, some herbicides, phthalate monoesters, fatty acids and fatty acid derivatives [3–6, 27]. However, a vast array of studies have highlighted species differences not just with respect to gene regulation [8, 9], but also in binding or activation of PPAR α [10–12]. For example, mouse and human PPAR α display differences in ligand binding, activation and physiological responses upon administration of certain hypolipidemic agonists, phthalate monoesters and LCFA [7, 10, 11]. The present study examines structural differences in the PPAR α proteins, which could be an underlying cause of species differences in ligand binding.

Molecular modeling simulations of hPPAR α -LBD and mPPAR α -LBD

The X-ray crystal structure of hPPAR α is composed of a helical sandwich and a four-stranded β -sheet. The Y-shaped PPAR α ligand binding pocket spans between the C-terminal helix 12 (containing the AF-2) and the 4 stranded β -sheet, splitting into 2 arms roughly parallel to helix 3 [2]. In order to investigate the mechanisms underlying differential binding and activation of mouse and human PPAR α in response to LCFA, the amino acid sequences of mPPAR α and hPPAR α were compared. While human and mouse PPAR α proteins (468 amino acids) bear approximately 92% sequence identity, there are 35 amino acid differences (Supplementary Figure 1). In the X-ray crystal structure of hPPAR α -LBD employed in this study (1K7L; 267 amino acids), 23 amino acids are different between the hPPAR α -LBD and the modeled structure of the mPPAR α -LBD. Regardless of this difference in amino acids, when we compared the energy minimized apo forms of hPPAR α -LBD and mPPAR α -LBD using Swiss PDB Viewer or the PyMOL Molecular Graphics System, there was no significant 3 dimensional structural difference between the two proteins (C α atoms RMSD < 0.05 $\text{\AA}^3$; data not shown). Similarly, no differences were noted in the Ramachandran plots of the two proteins (data not shown). This was consistent with previous data using circular

dichroism spectroscopy that demonstrated no significant differences in the secondary structural content of hPPAR α and mPPAR α [7].

Molecular docking simulations with hPPAR α -LBD and mPPAR α -LBD

For all docking simulations we utilized both AutoDock Vina [22] and the FlexiDock^{TM} module available on SYBYL®-X 2.0. In order to validate our docking simulations, we compared the energy minimized structure of hPPAR α -LBD + GW409544 obtained using our docking approaches to the experimentally obtained X-ray crystal structure of the same [2]. There was no significant difference between the two structures (C α RMSD < 0.01 Å³). Furthermore, the orientation of GW409544, as well as the amino acids participating in the interaction between GW409544 and the protein, was quite comparable in the two structures (Supplementary Fig. 2A and 2B). Thus, this docking protocol was considered suitable for subsequent docking runs. We next simulated the docking of GW409544 to our energy minimized model of mPPAR α -LBD. Although there was no significant difference between the RMSD value for the C α atoms (RMSD < 0.05 Å), the orientation of GW409544 was remarkably different in the hPPAR α -LBD and mPPAR α -LBD (Supplementary Fig. 2C and 2D). This was consistent with previous molecular modeling data which reported similar variations in the orientation and position of GW409544 within the ligand binding pockets of mPPAR α -LBD and hPPAR α -LBD [31]. It was proposed that part of these variances could be attributed to the bulky phenylalanine residue at 272 in mPPAR α -LBD (Isoleucine in hPPAR α -LBD), and that this may cause a large shift in the phenyloxazol arm of GW409544 (Supplementary Fig. 2D).

Upon validation of the docking parameters, the docking of LCFA to hPPAR α -LBD and mPPAR α -LBD were examined. Docking of saturated LCFA (palmitic and stearic acid) were preferentially examined, because mPPAR α and hPPAR α demonstrate differences in the binding to such LCFA [7]. Based on reported crystal structures and structure-activity relationships, most PPAR α agonists bind to PPAR α with the acidic head group forming hydrogen bonds with Y314 on helix 5 and Y464 on the AF-2 of helix 12. The hydrophobic tails of these ligands are stabilized by numerous hydrophobic interactions extending upward or downward in the 2 arms of the PPAR α pocket [2]. Based on these observations and the fact that LCFA serve to activate PPAR α , we expected the carboxylic acid group of the LCFA to form a specific hydrogen bonding network with Y314 and Y464 to stabilize the AF-2 helix, permitting PPAR α activation.

The binding mode of palmitic acid to hPPAR α -LBD demonstrated striking resemblance to that of other PPAR α agonists – stabilized by a combination of hydrogen bonds and hydrophobic interactions. The carboxylic acid group of palmitic acid was oriented towards the AF-2 helix forming hydrogen bonds with Y314 and Y464, and its hydrophobic tail was stabilized by numerous hydrophobic interactions in the core PPAR α pocket (Fig. 1A and Supplementary Fig. 3A). Similar docking poses were generated for another saturated (stearic acid; C18:0; Supplementary Fig. 4A), monounsaturated (palmitoleic acid; C16:1; Supplementary Fig. 4B) and polyunsaturated (docosahexaenoic acid; C22:6; Supplementary Fig. 4C) LCFA. The binding energies estimated by the docking software are presented in Table I. Although both AutoDock Vina and the SYBYL®-X 2.0 gave consistent and similar

output for the docking modes, the FlexiDock™ module on SYBYL®-X 2.0 was used to obtain binding energies associated with this docking. The FlexiDock™ module on SYBYL®-X 2.0 was chosen because 1) it permits both protein (sidechains) and ligands to carry flexible/rotatable bonds, and 2) the FlexiDock™ energy evaluation function is based on the Tripos Force Field which estimates the binding energy of the ligand, the receptor binding pocket, and the interaction between them. These results demonstrated that LCFA are bound in a similar manner as other PPAR α ligands and further support previous observations that suggest LCFA are high affinity endogenous ligands of hPPAR α [3, 7, 27].

While experimental results indicate that mPPAR α binds with strong affinity to monounsaturated and polyunsaturated LCFA, it binds only weakly to saturated LCFA [7]. Consistent to these observations, our docking simulations demonstrated that, with the exception of saturated LCFA, the binding modes and energies generated for the mPPAR α -LBD in complex with monounsaturated (C16:1; Supplementary Fig. 4A) and polyunsaturated (C22:6; Supplementary Fig. 4C) LCFA are quite comparable to that of hPPAR α -LBD. However, the conformation and position of saturated palmitic (Fig. 1C, Supplementary Fig. 3B) and stearic acid (Supplementary Fig. 4B) in the mPPAR α -LBD are remarkably different, demonstrating 4-fold higher binding energies (weaker binding) when compared to the docking poses in hPPAR α -LBD (Table I).

Two striking features were noted between the binding orientation of palmitic acid and stearic acid to mPPAR α -LBD compared to hPPAR α -LBD. Although multiple docking poses were generated, suggesting several possible conformations of the palmitic (or stearic) acid within the binding pocket, these characteristics were consistently seen in all poses for the mPPAR α -LBD. First, the carboxylic acid group did not form hydrogen bonds with the C terminal amino acids (important for AF-2 interaction) - possibly raising the binding energy (less negative or less favorable). Second, the acyl chain is not fully extended in the mPPAR α -LBD pocket (Fig. 1C, Supplementary Fig. 3B), and the fatty acid was unable to orient along the same axis as seen with the hPPAR α -LBD. This may raise the binding energy, resulting in weaker binding affinity of saturated LCFA to mPPAR α -LBD. It is known that saturated acyl chains normally prefer a fully extended conformation [32]. These results were consistent with the weaker binding affinities of saturated LCFA reported for mPPAR α [7]. While the computational and experimental binding trends are similar, it is noteworthy that the binding energies obtained in this study do not necessarily convert into the same nanomolar binding affinities reported experimentally. Such differences between computational binding energies and experimental binding affinities could in part be explained by parameters that are not taken into consideration in the docking simulations, including the effect of solvation, contribution of entropy, and the dynamic nature of proteins in solution. However, solvation itself is not likely to account for the large differences in LCFA binding by hPPAR α and mPPAR α . This is because the solvation energies of palmitic or stearic acid are about the same, regardless of the protein to which they are bound [33]. Further, the hydration of the binding pockets are also estimated to be similar, given the similar polarity of the amino acid substitutions at 272 and 279 (F272I and T279M). However, the overall protein flexibility and the role of water in this process are of particular importance. While these possibilities were not tested in this study, another factor that may play a crucial role in explaining such differences is the use of full-length PPAR α protein in

experimental ligand binding studies as compared to the use of only the PPAR α -LBD in computational docking simulations.

Comparison of the amino acid sequences from the human and mouse PPAR α -LBD, especially in helices 3, 5, 7 and 12 which form the central core of the ligand binding pocket, exhibit two major differences in helix 3, which occur at amino acid 272 (isoleucine to phenylalanine) and 279 (threonine to methionine). While both of these substitutions are fairly conservative, the amino acid at 272 in hPPAR α is an isoleucine with a small isobutyl group, whereas in mPPAR α this residue is a phenylalanine with a bulkier benzyl side chain. We speculated that the electron rich bulkier benzyl group of F272 in mPPAR α might cause steric hindrance and change the shape and volume of the mPPAR α ligand binding pocket (Fig. 1B, 1D). In order to test this hypothesis, we substituted the phenylalanine residue at 272 in the mPPAR α -LBD structure with an isoleucine (F272I mPPAR α -LBD).

The binding modes and energies generated using such an energy minimized model of F272I mPPAR α -LBD in complex with palmitic acid (Fig. 1E, Supplementary Fig. 3C), as well as palmitoleic, stearic and docosahexaenoic acids were similar to that obtained using the hPPAR α -LBD structure (Table I). These results suggest that the amino acid residue at position 272 of helix 3 plays a critical role in determining species specificity and selectivity of PPAR α ligands. The slight difference in the binding energy between hPPAR α -LBD and mPPAR α -LBD complexed with C22:6 may be attributed to the manner in which the ligand orients around the amino acid at 279 (threonine in hPPAR α and methionine in mPPAR α), although this possibility was not examined. This T279M substitution has previously been reported to cause differences in the activation of human and mouse PPAR α in response to synthetic PPAR α agonists [34].

To determine the contribution of these amino acids to the PPAR α ligand binding pocket, the binding pocket volumes were calculated using the POVME algorithm. Based on the occupancy of the GW409544 ligand (in 1K7L) and a padding variable set to 0.5 (deduced based on a carbon-hydrogen bond length of 1.09 Å), the ligand binding pocket of hPPAR α -LBD was 1177 Å³ (Fig. 1B). In contrast, the binding pocket of mPPAR α -LBD was 1073 Å³ (Fig. 1D). A single mutation of F272I or two mutations including both F272I and M279T in the mPPAR α -LBD resulted in binding pocket volumes of 1130 Å³ (Fig. 1F) and 1161 Å³ (data not shown), respectively. It is apparent from these results that the amino acid differences at residues 272 and 279 do alter the size of the pocket. However, as the average volume of a fatty acid (e.g. palmitic acid) is < 300 Å³, there is plenty of space within each of these pockets for fatty acid binding. This suggests that favorable interactions with the AF-2 domain (which are based on the orientation of the ligand) are more important for determining PPAR α ligand specificity, with regards to LCFA, than the total volume available within the pocket.

Purification of full-length recombinant F272I mPPAR α

In order to experimentally determine the effect of a phenylalanine to isoleucine substitution at amino acid 272 of mPPAR α , full-length recombinant F272I mPPAR α protein was expressed and purified as described for full-length mPPAR α and hPPAR α [7]. SDS-PAGE and Coomassie blue staining indicated a predominant band (>90%) of 52kDa corresponding

to the expected size of full-length F272I mPPAR α (Fig. 2B), with similar purity as mPPAR α (Fig. 2A). In both proteins, a small amount of tagged protein is seen at 75kDa (Fig. 2).

Binding of fluorescent fatty acids and fatty acyl-CoAs to F272I mPPAR α

While BODIPY fluorescence was low for each examined fluorophore in the absence of protein, titration of F272I mPPAR α with BODIPY C16-CoA resulted in increased fluorescence which approached saturation near 200 nM. (Fig. 3A, 3B). This data transformed into a linear double reciprocal plot (Fig. 3B, inset), consistent with a single binding site ($R^2 > 0.90$). Binding of BODIPY C16 fatty acid was also strongly saturable at a single binding site (Fig. 3C). Multiple replicates yielded K_d values of 55 ± 4 nM and 18 ± 3 nM for BODIPY C16-CoA and BODIPY C16 fatty acid, respectively, indicating high-affinity binding. These results were consistent with previously reported binding affinities of wild-type mPPAR α [7], suggesting that this amino acid change did not disrupt or alter the binding of these ligands.

Binding of endogenous LCFA and LCFA-CoA to F272I mPPAR α

In order to experimentally test the hypothesis that the F272I substitution could explain the differences in binding affinity of human and mouse PPAR α for saturated LCFA, the ligand specificity of F272I mPPAR α for naturally-occurring, endogenous LCFA and LCFA-CoA was examined. The binding affinities for naturally-occurring LCFA and LCFA-CoA were estimated by monitoring their ability to compete and displace BODIPY C16-CoA from F272I mPPAR α , which was observed as decreased BODIPY fluorescence. With the exception of lauric acid and lauroyl-CoA, titration with the fatty acids and fatty acyl-CoA examined here resulted in significantly decreased BODIPY fluorescence (Supplementary Fig. 5). Quantitative analyses of these data suggested strong binding ($K_i = 17$ –29 nM, Table II). By comparison, the synthetic PPAR α agonist clofibrate showed slightly weaker binding affinity ($K_i = 51$ nM), and the synthetic PPAR γ agonist rosiglitazone did not displace BODIPY C16-CoA (Supplementary Fig. 5L, Table II).

To confirm the ligand binding specificity of F272I mPPAR α , the binding affinity of LCFA and LCFA-CoA was also measured by spectroscopically monitoring the quenching of F272I mPPAR α aromatic amino acid emission. Titration of F272I mPPAR α with both palmitic (Fig. 4A) and stearic (Fig. 4C) acid (saturated LCFA) effectively quenched F272I mPPAR α fluorescence, yielding a sharp saturation curve with a maximal change at 100 nM. These data transformed into linear reciprocal plots (Fig. 4A, 4C insets), indicating high affinity binding at a single binding site (K_d of 20 nM and 11 nM for palmitic and stearic acids, respectively). With the exception of lauric acid (Fig. 4I) and lauryl-CoA (Fig. 4J), similar results were obtained for all examined fatty acids and fatty acyl-CoA (Fig. 4A–H), with single site binding affinities in the 11–27 nM range (Table II). The PPAR α agonist clofibrate strongly quenched F272I mPPAR α fluorescence (Fig. 4K), but displayed weaker affinity than the LCFA (Table II), while the PPAR γ agonist rosiglitazone showed no binding (Fig. 4L, Table II).

While the binding affinities obtained for F272I mPPAR α with saturated LCFA were comparable to those obtained with hPPAR α (K_d = 14–22 nM), they are significantly different (4–5 fold) from those obtained using wild-type mPPAR α (K_d = 81–135 nM, Supplementary Table I) [7]. These data further corroborate the importance of amino acid residue 272 in determining species selectivity for endogenous PPAR α ligands. LCFA-CoA binding was similar to previous reports for both mPPAR α and hPPAR α [7], suggesting that amino acid 272 is not as important for the orientation of these ligands within the pocket.

Effect of endogenous fatty acids and fatty acyl-CoAs on F272I mPPAR α secondary structure

Circular dichroism (CD) was used to examine whether the binding of LCFA or LCFA-CoA altered the F272I mPPAR α secondary structure. The far UV CD spectrum of F272I mPPAR α suggested the presence of substantial α -helical content, exhibiting a large positive peak at 192 nm and two negative peaks at 207 and 222 nm (Fig. 5A–E, filled circles). Quantitative analyses confirmed that F272I mPPAR α was composed of approximately 30 % α -helix, 18 % β -sheets, 22 % β -turns and 29 % unordered structures (Table III). A comparison of the CD spectra (Supplementary Fig. 6) and relative proportions of the secondary structures for wild-type hPPAR α , mPPAR α and F272I mPPAR α suggested no significant differences in the structure of these proteins - a finding consistent with our observations from the modeling data. This suggested that the F272I mutation in mPPAR α does not disrupt the secondary structure or folding of the protein.

The addition of high-affinity ligands to F272I mPPAR α resulted in conformational changes demonstrated by alterations in the molar ellipticity at 192, 207, and 222 nm (Fig. 5B–E), indicative of ligand binding. Conversely, no changes were observed with the addition of lauric acid (Fig. 5A), lauroyl-CoA (Fig. 5A) or rosiglitazone (Fig. 5F), consistent with the lack of binding of F272I mPPAR α to these ligands. While saturated LCFA do not induce secondary structural changes to mPPAR α [7], there was a significant decrease in the fraction of α -helical content and a concomitant increase in the fraction of β -sheets for F272I mPPAR α (Table III), similar to those reported for hPPAR α [7]. Similar helix-sheet transitions have been previously reported with other nuclear receptors and transmembrane proteins [27, 35, 36]. Most of the examined LCFA and LCFA-CoA resulted in F272I mPPAR α structural changes (Table III) most similar to those previously reported for hPPAR α [7], further indicating the importance of residue 272 in LCFA binding. However, palmitoyl-CoA and docosahexaenoic acid changes (Table III) were more similar to those reported for mPPAR α [7], suggesting that ligand structure may also be important in determining ligand orientation and binding.

Effect of fatty acids on transactivation of PPAR α -RXR α heterodimers

In order to determine whether residue 272 is also responsible for variances observed between mPPAR α and hPPAR α transactivation in response to saturated LCFA [7], luciferase reporter assays utilizing hPPAR α , mPPAR α and F272I mPPAR α were performed. Since PPAR α heterodimerizes with RXR α to induce transactivation, COS-7 cells were cotransfected with either pSG5 empty vector or a combination of hPPAR α and hRXR α , mPPAR α and mRXR α or F272I mPPAR α and mRXR α . The transactivation of a

PPRE×3 TK LUC reporter construct was analyzed in the absence or presence of ligands (Fig. 6). Transactivation was measured as percent firefly luciferase activity normalized to *Renilla* luciferase (internal control).

Cells overexpressing hPPAR α and hRXR α demonstrated significantly increased transactivation of the PPRE×3 TK LUC reporter in response to high-affinity ligands of hPPAR α (Fig. 6). In contrast, for cells overexpressing mPPAR α and mRXR α , only the examined unsaturated LCFA and clofibrate significantly increased transactivation. Consistent with the weak binding affinity of saturated LCFA for mPPAR α , addition of these ligands did not affect the activity in COS-7 cells. However, in cells overexpressing F272I mPPAR α and mRXR α , the addition of saturated LCFA (palmitic and stearic acid), as well as unsaturated LCFA (palmitoleic and docosahexaenoic acid) resulted in significantly increased transactivation, similar to clofibrate-treated cells (Fig. 6). This was consistent with the high-affinity binding of these ligands to F272I mPPAR α . In all treatments the addition of lauric acid, which consistently did not bind to hPPAR α , mPPAR α or F272I mPPAR α , had no significant effect on activity. These findings suggested that only high-affinity endogenous ligands increase PPAR α activity and, more importantly, the amino acid at 272 could be responsible for the differences in saturated LCFA-mediated transactivation of the PPRE×3 TK LUC reporter in cells overexpressing hPPAR α and mPPAR α .

These results are consistent with previous transactivation studies and gene expression studies which demonstrate species differences in the activity of human and mouse PPAR α in response to synthetic agonists such as 5, 8, 11, 14-eicosatetraynoic acid (ETYA), WY-14,643 and 2-ethylphenylpropanoic acid derivative (KCL), among others [8–11, 34, 37, 38]. While an I272F substitution diminished the agonistic activity of KCL, a T279M substitution increased the agonistic activity of WY-14,643 in hPPAR α [38]. Our studies with endogenous LCFA ligands suggest that, to a large extent, only amino acid 272 plays an important role in determining species differences, particularly for saturated LCFA. We speculate that based on the structure of ligands and their potential orientation and interactions within the PPAR α pocket, both amino acids at 272 and 279 are crucial determinants of species differences exhibited by PPAR α across species.

Computational and experimental data support the notion that amino acid substitutions could be responsible for differences in binding affinity and activation observed between human and mouse PPAR α . It is believed that during the course of evolution, emerging nuclear receptors acquired the ligand-binding capacities and further refined their specificities for a particular biologically significant ligand [39–41]. Among 117 vertebrate PPAR α protein coding sequences identified by BLAST, isoleucine 272 is conserved from bony fish to primates, with the exception of mouse (*Mus musculus*), rat (*Rattus norvegicus*) and two unrelated rodents: the naked mole rat (*Heterocephalus glaber*) and the thirteen-lined ground squirrel (*Ictidomys tridecemlineatus*). The distribution of these species suggests that the substitution of isoleucine for phenylalanine has evolved at least three times. A simple transversion (A to T) in the first position of the codon is enough to convert an isoleucine to a phenylalanine codon. However, given the high evolutionary rate of PPAR α [39–41], the conservation of isoleucine in this position implies that there are functional and evolutionary consequences associated with this change (e.g. it is under purifying selection). Consistent

with this, our results indicated that compared to humans, the I272F amino acid change seen in mouse represents a partial loss of function mutation (hypomorphic) with respect to LCFA binding. Whether this change is responsible for the increased sensitivity of mouse to peroxisome proliferation or hepatic cancer remains to be determined, but the single F272I substitution in mPPAR α recapitulates the human-like LCFA binding and trans-activation functions. Other amino acid positions examined that were not predicted to alter LCFA binding energies (such as position 279) displayed much greater variation among species, suggesting more relaxed functional and evolutionary constraints at those positions.

One could speculate that PPAR α underwent strong selective pressure that was directly affected by dietary changes and that this eventually provided crucial structural and functional changes like I272F in mouse. However, there is no clear dietary or metabolic relationship uniquely shared among the four species that harbor the I272F amino acid change, and compensatory mechanisms that may allow this mutation to persist within these species are not clearly established. Therefore, the important question that still remains unsolved is why such differences in PPAR α structure would exist.

Nonetheless, we demonstrated for the first time that differences in amino acids in the LBD of PPAR α contribute to species selectivity and specificity for endogenous PPAR α ligands. The importance of PPAR α in human disease is validated by the lipid lowering effects of synthetic PPAR α agonists. The data presented herein enhances our understanding of dietary effects on PPAR α and may aid in the development of more targeted therapeutics. Moreover, these data demonstrate the efficacy of molecular modeling and docking simulations for examining the effect of structural variations on ligand binding.

Abbreviations

PPARα	peroxisome proliferator-activated receptor alpha
DBD	DNA binding domain
LBD	ligand binding domain
RXRα	retinoid X receptor alpha
LCFA	long-chain fatty acids
LCFA-CoA	long-chain fatty acyl-CoA
mPPARα	mouse PPAR α

hPPARα	human PPAR α
F272I mPPARα	mutant form of mPPAR α that has a Phe to Ile substitution at position 272, 6xhis, polyhistidine tag
PPRE	peroxisome proliferator response element
ACOX	acyl-CoA oxidase

Highlights

- Mechanisms underlying divergence in endogenous ligand binding affinities of human and mouse PPAR α were examined
- The size and shape of the PPAR α ligand binding pocket differ between mouse and human
- A phenylalanine at 272 in mouse PPAR α causes steric hindrance and inhibits binding of saturated fatty acids
- A F272I amino acid substitution in mPPAR α recapitulates the hPPAR α saturated fatty acid binding and activation capabilities

Fig. 1.

Comparison of the binding modes of C16:0 complexed with (A) hPPAR α LBD, (C) mPPAR α LBD and (E) F272I mPPAR α LBD. All docking poses presented here were generated using the FlexiDock^{TM} module available on SYBYL® - X 2.0 and are comparable to those generated using AutoDock Vina. In the left-hand figures AF2 helix 12, helix 3 and helix 5 are depicted in red, cyan and green respectively. The middle panel figures are close-up views of respective panels from the left. The ligand is colored in magenta and the amino-acids Tyr 314, Tyr 464 and Ile-272 or Phe-272 are labeled. The figures on the right represent the comparison of the ligand binding cavities of (B) hPPAR α -LBD, (D) mPPAR α -LBD and (F) F272I mPPAR α -LBD. The volumes of the ligand binding pockets were determined to be 1177 Å³ (hPPAR α -LBD; blue), 1073 Å³ (mPPAR α -LBD; red), and 1130 Å³ (F272I mPPAR α -LBD; orange). The amino acid residues at 272 and 279 are labeled.

Fig. 2. SDS-PAGE and Coomassie blue staining of 1 μg, 3 μg and 6 μg of purified recombinant (A) mPPARα (left) and (B) F272I mPPARα showing relative purity of the protein. The prominent band at 52 kDa represent full-length, untagged recombinant mPPARα and F272I mPPARα.

Fig. 3.

(A) Corrected fluorescence emission spectra of 0.1 μ M F272I mPPAR α titrated with 0 (filled circles), 20 (open circles), 50 (filled triangles), 100 (open triangles), 200 (filled squares) and 300 nM (open squares) of BODIPY C16-CoA upon excitation at 465 nm. These results demonstrate increased fluorescence intensity upon binding to F272I mPPAR α . Plot of F272I mPPAR α fluorescence emission at 515 nm (excitation 465 nm) as a function of BODIPY C16:0-CoA (B) and BODIPY C16:0 FA (C). Insets represent double reciprocal plots of the binding curve from each panel. All values represent the mean $\pm$ S.E., $n = 3$.

Fig. 4.

Interaction of naturally-occurring fatty acids and fatty acyl-CoA with F272I mPPAR α .

Direct binding assay based on quenching of F272I mPPAR α aromatic amino acid fluorescence emission (excitation = 280 nm and emission = 300–400 nm) when titrated with the following ligands: (A) palmitic acid, (B) palmitoleic acid, (C) stearic acid, (D) docosahexaenoic acid, (E) palmitoyl-CoA, (F) palmitoleoyl-CoA, (G) stearoyl-CoA, (H) docosahexaenoyl-CoA, (I) lauric acid, (J) lauroyl-CoA, (K) clofibrate, and (L) rosiglitazone. Data are presented as the change in fluorescence intensity ($F_0 - F_i$) plotted as a function of ligand concentration. Insets represent linear plots of the binding curve from each panel. All values represent mean $\pm$ S.E., $n = 3$.

Fig. 5.

Far UV circular dichroic (CD) spectra of F272I mPPAR α in the absence (filled circles) and presence of added ligand: A, Lauric acid (open circles) or Lauryl CoA (filled triangles); B, palmitic acid (open circles) or palmitoyl CoA (filled triangles); C, palmitoleic acid (open circles) or palmitoleoyl-CoA (filled triangles); D, stearic acid (open circles) or stearoyl-CoA (filled triangles); E, docosahexanoic acid (open circles) or docosahexaenoyl-CoA (filled triangles); and F, clofibrate (open circles) or rosiglitazone (filled triangles). Each spectrum represents an average of 10 scans for a given representative spectrum from at least three replicates.

Fig. 6.

Fatty acids mediate species-selective transactivation of PPAR α -RXR α heterodimers. Cos7 cells transfected with either both hPPAR α and hRXR α , both mPPAR α and mRXR α , or both F272I mPPAR α and mRXR α analyzed for transactivation of the acyl-CoA oxidase reporter construct in presence of vehicle (*open bars*), 1 μ M lauric acid (*diagonally upward bars*), 1 μ M palmitic acid (*hatched bars*), 1 μ M palmitoleic acid (*diagonally downward bars*), 1 μ M stearic acid (*horizontally lined bars*), 1 μ M docosahexanoic acid (*open bars*) and 1 μ M clofibrate (*diagonally upward bars*). The y-axis represents values for firefly luciferase activity that have been normalized to *Renilla* luciferase (internal control) as well as controls for cells transfected with empty pSG5 vector. The bar graph represents the mean values ($n = 3$) $\pm$ standard error. * $P < 0.01$, ** $P < 0.001$.

Table I

Comparison of binding energies (kcal/mol) for mouse and human PPAR α LBD complexed with LCFA ligands.

Ligand	Chain length: double bonds (position)	hPPAR α kcal/mol	mPPAR α kcal/mol	F272I mPPAR α kcal/mol
Palmitic acid	C16:0	-1150	-284	-1089
Palmitoleic acid	C16:1 (n-7)	-1149	-1143	-1149
Stearic acid	C18:0	-1153	-298	-1112
Docosahexanoic acid	C22:6 (n-3)	-1187	-932	-1039

Binding energies were derived using the FlexiDock^{TM} module available on SYBYL® - X 2.0 (Tripos, St. Louis, MO).

Affinity of F272I mPPAR α for non-fluorescent ligands determined by quenching of hPPAR α aromatic amino acid fluorescence and by displacement of F272I mPPAR α -bound BODIPY C16-CoA.

Table II

Ligand	Chain length: double bonds (position)	K_d (nM) Fatty acid	K_d (nM) Fatty acyl-CoA	K_i (nM) Fatty acid	K_i (nM) Fatty acyl-CoA
Lauric acid/CoA	C12:0	ND	ND	ND	ND
Palmitic acid/CoA	C16:0	20 $\pm$ 3	17 $\pm$ 2	19 $\pm$ 2	18 $\pm$ 2
Palmitoleic acid/CoA	C16:1 (n-7)	19 $\pm$ 3	21 $\pm$ 2	22 $\pm$ 3	28 $\pm$ 3
Stearic acid/CoA	C18:0	11 $\pm$ 2	18 $\pm$ 2	15 $\pm$ 1	19 $\pm$ 2
Docosahexanoic acid/CoA	C22:6 (n-3)	17 $\pm$ 3	27 $\pm$ 3	17 $\pm$ 2	29 $\pm$ 3
Clofibrate		42 $\pm$ 6		51 $\pm$ 3	
Rosiglitazone		ND		ND	

Values represent the mean $\pm$ S.E. (n = 3). ND, not determined.

Table III

Effect of ligands on the relative proportion of F272I mPPAR α secondary structure determined by CD. These structures were as follows: total helices (H; a sum of regular α -helices and distorted α -helices), total sheets (S; a sum of regular β -sheets and distorted β -sheets), turns (Trn; β -turns), and unordered (Unrd) structures.

Average	Total H $\pm$ S.E.	Total S $\pm$ S.E.	Trn $\pm$ S.E.	Unrd $\pm$ S.E.
F272I mPPAR α	30 $\pm$ 2	18.3 $\pm$ 2.3	21.8 $\pm$ 0.2	28.8 $\pm$ 0.2
F272I mPPAR α + Lauric acid	29 $\pm$ 1	21 $\pm$ 2	21.8 $\pm$ 0.1	28.9 $\pm$ 0.2
F272I mPPAR α + lauryl-CoA	30 $\pm$ 1	20 $\pm$ 1	21.7 $\pm$ 0.3	29.1 $\pm$ 0.1
F272I mPPAR α + palmitic acid	18.1 $\pm$ 0.2**	31.5 $\pm$ 0.5**	22 $\pm$ 0.1	28.6 $\pm$ 0.3
F272I mPPAR α + palmitoyl-CoA	21 $\pm$ 2*	29 $\pm$ 1*	22.1 $\pm$ 0.3	29.1 $\pm$ 0.2
F272I mPPAR α + palmitoleic acid	20 $\pm$ 1 [#]	30 $\pm$ 1 [#]	21.7 $\pm$ 0.1	28.7 $\pm$ 0.2
F272I mPPAR α + palmitoleoyl-CoA	22 $\pm$ 2*	28 $\pm$ 1*	21.4 $\pm$ 0.2	28.5 $\pm$ 0.5
F272I mPPAR α + stearic acid	18.3 $\pm$ 0.1**	31.1 $\pm$ 0.1**	21.9 $\pm$ 0.1	28.5 $\pm$ 0.1
F272I mPPAR α + stearyl-CoA	20 $\pm$ 1*	29 $\pm$ 1*	21.5 $\pm$ 0.2	28.7 $\pm$ 0.3
F272I mPPAR α + DHA	19 $\pm$ 1**	30.8 $\pm$ 0.3**	21.5 $\pm$ 0.1	28.7 $\pm$ 0.1
F272I mPPAR α + DHA-CoA	19.1 $\pm$ 0.1 [#]	30.6 $\pm$ 0.3**	22 $\pm$ 1	28.6 $\pm$ 0.1
F272I mPPAR α + Clofibrate	17.1 $\pm$ 0.1**	31.9 $\pm$ 0.3**	22 $\pm$ 1	29.0 $\pm$ 0.2
F272I mPPAR α + Rosiglitazone	31 $\pm$ 1	19 $\pm$ 1	21.9 $\pm$ 0.1	28.6 $\pm$ 0.1

Asterisks represent significant differences between F272I mPPAR α only and F272I mPPAR α in the presence of added ligand (* $P < 0.05$, ** $P < 0.001$ and [#] $P = 0.001$).
