Abstract

RATIONALE—Although nicotine exposure upregulates the $\alpha 4\beta 2^*$ subtype of nicotinic acetylcholine receptors (nAChRs), the upregulation of nAChRs in non-human primates voluntarily self-administering nicotine has never been demonstrated.

OBJECTIVES—Determine if short access to nicotine in a non-human primate model of nicotine self-administration is sufficient to induce nAChRs upregulation.

METHODS—We combined a nicotine self-administration paradigm with *in vivo* measure of $\alpha 4\beta 2^*$ nAChRs using 2-[¹⁸F]fluoro-A-85380 (2-FA) and positron emission tomography (PET) in

six squirrel monkeys. PET measurement was performed before and after intravenous nicotine self-administration (unit dose 10 µg/kg per injection). Monkeys were trained to self-administer nicotine under a fixed-ratio (FR) schedule of reinforcement. Intermittent access (one hour daily per weekday) to nicotine was allowed for four weeks and levels of $\alpha 4\beta 2^*$ nAChRs were measured four days later.

RESULTS—This intermittent access was sufficient to induce upregulation of $\alpha 4\beta 2^*$ receptors in the whole brain (31 % upregulation) and in specific brain areas (+36 % in amygdala and +62 % in putamen).

CONCLUSIONS—These results indicate that intermittent nicotine exposure is sufficient to produce change in nAChRs expression.

positron emission tomography; nicotine self-administration; *in vivo* binding; non-human primates

INTRODUCTION

The $\alpha 4\beta 2^*$ subtype of the nicotinic acetylcholine receptor (nAChR) has been implicated in mediating the reinforcing effects of nicotine (Maskos et al. 2005). Studies in transgenic mice have revealed that $\beta 2$ subunit deletion decreases sensitivity to nicotine's reinforcing effects while overexpression of the $\alpha 4$ subunit increases sensitivity to nicotine reinforcement (Picciotto et al. 1998; Tapper et al. 2004). However the relationship between nAChRs expression and motivation for nicotine intake is complex since lower levels of midbrain nAChRs have been associated with a high motivation to self-administer nicotine (Le Foll et al. 2009).

It is well known that nicotine exposure produces an upregulation of high-affinity nAChRs in the brain (see (Govind et al. 2009) for a review). Based on postmortem brain tissue studies, the density of nAChRs is greater in smokers compared to non-smokers, whereas the density in non-smokers is identical to that in ex-smokers (Benwell et al. 1988; Breese et al. 1997; Perry et al. 1999). This upregulation has been shown in nonhuman primates (as in (Staley et al. 2006) with oral nicotine administration for example). Nicotine-treated rodents also display enhanced nAChRs density compared to control animals (Besson et al. 2007; Marks et al. 1983; Schwartz and Kellar 1983). Since there are no associated changes of mRNA coding for these receptors, post-transcriptional mechanisms have been proposed to underlie these changes (Govind et al. 2009). Further, the functional role of this receptor upregulation is still unclear (Picciotto et al. 2008; Picciotto and Mineur 2014; Wonnacott 1990).

Although initial experiments to study nAChRs upregulation were performed on rodent brain preparations using binding techniques (Flores et al. 1997; Flores et al. 1992), it is feasible to explore nAChRs expression *in vivo* using Positron Emission Tomography (PET). Different PET radiotracers have been developed for $\alpha 4\beta 2^*$ nAChRs quantification (Horti et al. 2013). Among those PET radiotracers, 2-[^{18}F]fluoro-A-85380 (2-FA) has been used in rodents (Vaupel et al. 2007), non-human primates (Chefer et al. 2003; Le Foll et al. 2007a; Le Foll et al. 2009; Valette et al. 2003; 2005) and human subjects (Mukhin et al. 2008), with an

upregulation of nAChRs reported in human smokers (Brody et al. 2013; Mukhin et al. 2008; Wullner et al. 2008). Similar nAChR upregulation in the brains of smokers has been observed using a Single Photon Emission Computed Tomography and analog of 2FA, 5- ^{123}I iodo-A-85380 (Staley et al. 2006).

Due to the ability to tightly control environmental factors and drug exposure history, PET imaging studies in non-human primates have contributed extensively to our understanding of psychostimulant drug addiction (Gould et al. 2014; Howell and Wilcox 2002). However, much less is known about nicotine as compared to cocaine administration. This is likely due to the fact that few research centers have the ability to assess nAChRs in non-human primates with PET imaging along with the ability to study the nicotine dependence process using a drug self-administration paradigm (Le Foll et al. 2007b). Combining these two approaches, an inverse relationship has been found between the baseline midbrain expression of $\alpha 4\beta 2^*$ nAChRs and the motivation to self-administer nicotine in squirrel monkeys (Le Foll et al. 2009). It is not clear if intermittent access to nicotine, as currently used in a well-developed non-human primate model of nicotine self-administration (Le Foll et al. 2007b), is sufficient to upregulate nAChRs. In order to test this hypothesis, we trained squirrel monkeys to self-administer nicotine under a Fixed Ratio schedule of reinforcement with one-hour daily sessions. Pre-exposure baseline and post-exposure levels of nAChRs were measured using the binding potential (BP_{ND}) of 2- ^{18}F fluoro-A-85380 (2-FA), a selective $\alpha 4\beta 2^*$ nAChR PET ligand. BP_{ND} is proportional to the density of receptors available for radioligand binding (Bavai) *in vivo*. $\text{BP}_{\text{ND}} = f_{\text{ND}} \cdot \text{Bavai} / K_{\text{D}}$, where K_{D} is the dissociation constant and f_{ND} is a free fraction of radioligand in nondisplaceable compartment (Innis et al. 2007). Nicotine upregulates nAChRs in both an intracellular compartment and on cell surface (Kuryatov et al. 2005; Lester et al. 2009; Lomazzo et al. 2011; Zambrano et al. 2012; Zambrano et al. 2015). Therefore it is reasonable to expect the presence of nicotine-induced upregulation of nAChRs in practically all brain regions expressing nicotinic receptors. Indeed, it was shown that in comparison with non-smokers smokers have significant increases of nAChRs across almost the entire brain (Mukhin et al. 2008). Therefore our primary hypothesis was that post-exposure levels of nAChRs in total monkey brain will be higher as compared to pre-exposure baseline levels. As an exploratory analysis and for the purpose of comparison with receptor upregulation in smokers, we also have evaluated pre- and post-exposure levels of nAChRs in a few regions of reasonable size in the squirrel monkey brain and/or were previously assessed for nAChR upregulation in smoker's brain with 2FA (Mukhin et al. 2008).

MATERIAL AND METHODS

Subjects

Six adult drug-naïve male squirrel monkeys (*Saimiri sciureus*), weighing 710 to 950 g, were housed individually in a temperature- and humidity-controlled room and were maintained on a 12-h light/dark cycle; the lights were on from 6:45 AM to 6:45 PM. Experiments were conducted during the light phase. Monkeys were maintained in facilities fully accredited by the American Association for the Accreditation of Laboratory Animal Care (AAALAC) and all experimentation was conducted in accordance with the guidelines of the Institutional

Care and Use Committee of the Intramural Research Program, National Institute on Drug Abuse, National Institutes of Health, and the Guide for Care and Use of Laboratory Animals (National Research Council 2003).

PET imaging studies—Radiochemistry: [^{18}F]Fluoride was produced using an RDS111 negative ion cyclotron, and 2-FA was synthesized using a modified semiautomated method (Horti et al. 1998). The final product was formulated as a sterile and pyrogen-free isotonic solution. Radiochemical purity product was greater than 98% and specific activity was in the range from 106 to 648 GBq/ μmol (313 ± 166 GBq/ μmol , average $\pm$ SD).

PET and MRI scanning procedures—Data were acquired on a Siemens Exact ECAT HR+ tomograph (63 slices, center to center spacing of 2.4 mm, with an in-plane reconstructed resolution, full width at half maximum (FWHM), of 4.7 mm at the center of the field of view and reconstructed axial spatial resolution of 4.2 mm in 3D mode). Before each radioligand administration, transmission scans were obtained with three rotating ^{68}Ge - ^{68}Ga sources and used to correct for photon attenuation by tissue and facemask. PET images were reconstructed from the raw data with a standard filtered-back projection algorithm and a RAMP filter. For the PET scans, monkeys were initially anesthetized with 1.5 mg/kg alfadolone and alfaxolone acetate (Saffan[®], Arnolds Veterinary Products, Shropshire, U.K.), given intramuscularly. Anesthesia was then maintained by 1.5–2.5% isoflurane. An individually molded thermoplastic facemask was secured to a custom-made monkey head-holder attached to a backboard.

Acquisition of dynamic PET scans started with the injection of 2-FA as a bolus (39 ± 11 MBq/kg injected intravenously in approximately 1 ml of saline over 20 sec) and continued for 5 hours.

Anatomical MRI brain images were acquired on a 3.0 Tesla Siemens Magnetom Allegra MRI unit (Siemens Medical Solutions) using continuous intravenous infusion of 8–11 mg/kg/h Saffan to maintain anesthesia.

Vital signs, including heart rate, ECG (during PET studies), respiration rate, ET_{CO_2} and blood oxygen saturation (always maintained above 95%), were continuously monitored during the PET and MRI imaging sessions.

PET data analysis—Regions of interest (ROIs) for the whole brain, cerebellum, thalamus, pons, amygdala, putamen and temporal cortex were defined on the individual T1 MRI images co-registered to PET images, with reference to a stereotaxic atlas (Gergen and MacLean 1962). ROIs for muscle were placed on the back of the neck in the area of the semispinalis cervicis, splenius capitis, and obliquus capitis muscles. BP_{ND} values were calculated using a simplified reference tissue model (PMOD v. 3.17) with muscles as a reference region. BP_{ND} values were corrected for differences between brain tissue V_{ND} and muscle V_{T} using equation (6) from (Le Foll et al. 2007a).

$$\text{BP}_{\text{ND}} = \frac{\text{BP}_{\text{msl}} + 1}{\alpha} - 1$$

Previously, using an averaged 2-FA volumes of distribution (VD), VD_T value in muscle (3.02 ± 0.24 ; $n=15$) and an averaged VD_{ND} value for thalamus, cortex and midbrain obtained from blocking studies with nicotine pumps in squirrel monkeys (4.06 ± 0.21 , $n=4$), we obtained the α value (the ratio of VD_{ND} over muscle VD_T) of 1.34 (Le Foll et al. 2007a).

First, BP_{ND} values for the whole brain were compared before and after self-administration using paired t-test. Subsequently, cerebellum, thalamus, pons, amygdala, putamen and temporal cortex regions were compared before and after self-administration using paired t-test. Results were corrected for multiple comparisons using Holm–Bonferroni method.

Intravenous nicotine self-administration

Several days after the first PET scan, acquisition sessions were initiated during which the monkeys were allowed to self-administer nicotine intravenously under a fixed-ratio schedule of reinforcement. The ratio requirement was gradually increased up to the final ratio requirement (FR-10). Session duration was one hour and SA sessions were conducted during weekdays. Once self-administration was stable, the monkeys got access to four weeks of nicotine self-administration with a unit dose of 10 $\mu\text{g/kg}$ per injection. The unit dose of 10 $\mu\text{g/kg}$ nicotine per injection was selected, as this dose had previously been reported to maintain self-administration at high rates under both fixed and progressive ratio schedule of reinforcement in squirrel monkeys under those conditions (Le Foll et al. 2007b). 10 $\mu\text{g/kg}$ per injection was also the unit dose that maintained the highest level of responding under FR10 schedule of reinforcement (Le Foll et al. 2007b). The following week after four days, the post-exposure PET sessions were performed. The four day interval between nicotine access and PET was chosen as previous studies indicates that binding of imaging tracers could be affected in early withdrawal (Staley et al. 2006). Previous studies with human subjects and 2-FA indicated that four days is sufficient to decrease plasma nicotine to levels at which it will not compete with the PET radioligand for binding sites (Mukhin et al. 2008) and some pilot data (Le Foll et al, unpublished personal observations) supported the use of the four day withdrawal phase in squirrel monkeys.

RESULTS

Behaviorally, the nicotine self-administration behavior remained stable over the four-week exposure period. There was a significantly higher number of FR completed on the active vs the inactive lever (see Fig.1, $P<0.00001$) and there was no fluctuation of the number of active lever presses over the four weeks of testing (NS).

The typical distribution of 2FA BP_{ND} in squirrel monkey brain before and after nicotine self-administration of nicotine is shown in Fig.2. ROI data analysis indicated a 31 % increase of 2-FA BP_{ND} in the whole brain compared to baseline, $P=0.005$ (Fig. 3A). After correcting for multiple testing, there was a significant increase of BP_{ND} in the Amygdala (+36 %, $P=0.006$) and Putamen (+62 %, $P=0.002$). Increased binding in the cerebellum, thalamus, pons and temporal cortex did not survive multiple comparison corrections.

We performed correlations between the number of nicotine infusions (average infusions during the four weeks and average infusions during the last two days of the four weeks) and

the percentage of $\alpha 4\beta 2^*$ nAChRs upregulation. Unexpectedly,, no significant correlations were found (data not shown). However, due to the small sample size, we may have been underpowered to detect such relationship between upregulation and nicotine exposure.

DISCUSSION

Here, we report that stable four weeks of nicotine self-administration (10 ug/kg/injection) in squirrel monkeys is sufficient to produce upregulation of $\alpha 4\beta 2^*$ nAChRs. That nicotine is an effective reinforcer in squirrel monkeys has been previously shown (Goodwin et al. 2015; Le Foll et al. 2007b). Indeed, the first report of nicotine's reinforcing properties was generated in squirrel monkeys trained to respond under a second order schedule of reinforcement (Goldberg et al. 1981). This seminal report had a tremendous influence in the field and led subsequently to the Surgeon General report indicating that nicotine was addictive (Department of Health and Human Services 1988). The conditions under which nicotine functions as an effective reinforcer of drug use have been clearly identified and are used to study nicotine addiction processes (Justinova et al. 2015a; Le Foll et al. 2009; Le Foll et al. 2007b; Mascia et al. 2011). The present findings are in agreement with those previous reports. Although the monkeys in our study had a slightly different exposure to nicotine (due to their differential number of voluntarily self-administer infusions of nicotine), we felt that it was more valid to use a contingent method of administration as compared to a non-contingent method of nicotine administration (Jacobs et al. 2003).

The innovative aspect of this research consists of combining the PET imaging with the extended nicotine SA paradigm. The distribution and density of $\alpha 4\beta 2^*$ nicotinic receptors assessed by 2-FA BP_{ND} before and after self-administration is consistent with previously published data in an acute nicotine access model (Le Foll et al. 2007a; Le Foll et al. 2009). Notably, we found that the highest density of a $\alpha 4\beta 2^*$ receptors is observed in the thalamus, whereas other brain areas displayed lower BP_{ND}. The lowest binding was observed in the cerebellum. This result is in agreement with previous PET studies performed in humans (Kimes et al. 2003; Mukhin et al. 2008). Although the overall pattern of expression of nAChRs was not dramatically changed following the self-administration sessions, we observed a significant elevation of BP_{ND} in the whole brain as well as in the amygdala and putamen. The brain area with the lowest upregulation was the thalamus and this result is consistent with the absence of higher densities determined with 2-FA reported in the thalamus in smokers vs non-smokers (Mukhin et al. 2008). In other brain areas the upregulation was measured from 22 to 62 %, which is about two times smaller than that observed using PET and 2FA in human smokers (Mukhin et al. 2008). It is possible that the smaller upregulation observed in some areas may be related to underestimation of radioactivity concentration in squirrel monkey brain structures as a result of greater partial volume effect compared with humans.

Concerning the analysis of the PET data, in this study we were not able to use CB as a reference region for receptor quantifications. Though previously we were able to demonstrate that untreated squirrel monkeys have very low levels of nAChRs in CB and that this region can be used for calculation of brain BP_{ND} at this condition (Le Foll et al. 2007a), it seems that such an approach is not suitable for brain nAChR quantification after treatment

with nicotine. As shown in Fig. 3, nicotine self-administration results in the upregulation of nAChRs in CB, which would result in the underestimation of brain region BP_{ND} values after treatment and therefore leads to the underestimation of nicotine-induced receptor upregulation. To overcome this obstacle in the present study we have employed our previously developed and evaluated method utilizing neck muscle as a reference region (Le Foll, Chefer et al. 2007).

This study has several limitations. The first one is the small sample size. Second, we have only included male squirrel monkeys and sex may be a factor influencing 2-FA binding, so we cannot determine that similar results would have been obtained in female subjects. Another limitation is that changes in BP_{ND} can be produced not only by the changes in receptor density, but also could be produced by changes in receptor affinity and/or receptor occupancy by acetylcholine, which we did not explore here. Finally, we did not measure plasma nicotine or the concentration of nicotine in the brain at the time of post-exposure scan. Therefore we cannot exclude the presence of residual nicotine in the brain which may have interfered with the binding of 2-FA (Staley et al. 2006). It is also possible that during the four day interval between the cessation of nicotine exposure and the PET scan, the receptor upregulation may have decreased, but we could not perform the scan earlier due to the possible presence of nicotine within the brain. Another clear limitation is the fact that those findings do not allow any conclusions to be drawn about the functional role of this upregulation. However, a recent study evaluating the response to nicotine patches in human smokers indicates that the smokers with less upregulation of available $\alpha 4\beta 2^*$ nAChRs are more likely to quit after treatment, as compared to smokers with more upregulation (Brody et al. 2014). This suggests that this receptor's upregulation may be of importance in the smoking cessation process. Nonetheless the additional studies are required to determine if this upregulation could represent a therapeutic target.

CONCLUSION

Although these results should be duplicated with a larger group of animals, this report is the first to explore upregulation of nAChRs in non-human primates trained to self-administer nicotine. It appears that the model of short access to nicotine as used to screen for medication discovery (see Justinova et al. 2015a; Justinova et al. 2015b; Mascia et al. 2011) is capable of inducing the same upregulation as described in the brains of human smokers. This research suggests that this upregulation may be associated with the early development of nicotine addiction and its functional role should be explored further.

FIGURE 1.

Responding on the active lever and inactive lever under the fixed-ratio 10 schedule of reinforcement maintained by 10 µg/kg/injection dose of nicotine. Average lever presses ($\pm$ SEM) are shown over consecutive week days for 4 weeks. Data obtained in six non-human primates.

FIGURE 2.

BP_{ND} images of squirrel monkeys brain acquired with 2FA before (Pre SA) and after (Post SA) nicotine self-administration. The images illustrate the representative results from a single animal. Similar results were obtained in five additional animals. The first column represents the structural T1 brain MRI images.

FIGURE 3.

$\alpha 4\beta 2^*$ nAChRs (BP_{ND} of 2-FA) at the level of the whole brain (**A**) or specific brain areas (**B**). Results are expressed as average BP_{ND} ($\pm$ SEM). Cb: Cerebellum; Th: Thalamus; Po: Pons; Am: Amygdala; Put: Putamen; Temp: Temporal Cortex. Uncorrected T test are presented. * $P < 0.05$.
