Abstract

Objective—Parkinson's disease (PD) is associated with deficits in social cognition and visual perception, but little is known about how the disease affects perception of socially complex biological motion, specifically motion-defined communicative and non-communicative gestures. We predicted that individuals with PD would perform more poorly than normal control (NC) participants in discriminating between communicative and non-communicative gestures, and in describing communicative gestures. We related the results to the participants' gender, as there are gender differences in social cognition in PD.

Method—The study included 23 individuals with PD (10 men) and 24 NC participants (10 men) matched for age and education level. Participants viewed point-light human figures that conveyed communicative and non-communicative gestures and were asked to describe each gesture while discriminating between the two gesture types.

Results—PD as a group were less accurate than NC in describing non-communicative but not communicative gestures. Men with PD were impaired in describing and discriminating between communicative as well as non-communicative gestures.

Conclusion—The present study demonstrated PD-related impairments in perceiving and inferring the meaning of biological motion gestures. Men with PD may have particular difficulty in understanding the communicative gestures of others in interpersonal exchanges.

MeSH Keywords

Neurodegenerative Diseases; Gender; Interpersonal Relations; Motor Activity; Social Behavior; Biological Motion

Introduction

Parkinson's disease (PD) is a progressive neurodegenerative disorder associated with the death of dopaminergic neurons in the substantia nigra. Because of strong functional connections between the basal ganglia and neural regions involved in social cognitive

processing, individuals with PD experience problems in social cognition, including difficulty recognizing emotions from faces and prosody (Buxton, MacDonald, & Tippet, 2013; Clark, Nearing, & Cronin-Golomb, 2008; Dara, Monetta, & Pell, 2008), as well as in theory of mind (Bodden, Dodel, & Kalbe, 2010; Freedman & Stuss, 2011). Deficits in social cognition in PD are associated with changes in orbitofrontal cortex, cingulate gyrus, temporo-parietal cortex, and the amygdala (Ibarretxe-Bilbao et al., 2009; Péron et al., 2010), as well as white matter integrity (Baggio et al., 2012). These deficits arise in part from impairments in cognitive function (e.g., working memory, visuospatial skills; Pell et al., 2014; Yip, Lee, Ho, Tsang, & Li, 2003), but can also manifest independently of cognitive deficits (Bodden, Mollenhauer, et al., 2010; Gray & Tickle-Degnen, 2010).

A limitation of previous studies in the visual modality is that they have predominantly focused on the perception and recognition of *static* stimuli such as emotional faces. Few studies have investigated how PD affects the perception of *dynamic* social information. Human body motion, or biological motion, enables the effective communication of social intentions and emotions (Atkinson, Dittrich, Gemmell, & Young, 2004; Roether, Omlor, Christensen, & Giese, 2009). Whether shaking a fist vigorously to convey anger or rubbing one's stomach to communicate satisfaction following a tasty meal, communicative (also known as intransitive) gestures are a ubiquitous and important part of interpersonal communication. Transitive gestures that are object-oriented (e.g., hammering, throwing a ball) are also important as they allow observers to perceive and understand actions and activities that others are engaged in.

Gesture perception from biological motion may be impaired in PD. A recent investigation from our group found that individuals with PD are less sensitive than healthy adults to biological motion that depicts walking (Jaywant et al., submitted), a deficit that may extend to more socially complex biological motion. Gesture perception activates the superior temporal sulcus (STS) and premotor cortex (Lotze et al., 2006; Montgomery, Isenberg, & Haxby, 2007), which are critical regions in biological motion perception (Gilaie-Dotan, Kanai, Bahrami, Rees, & Saygin, 2013; Grossman, Battelli, & Pascual-Leone, 2005) and have compromised neural integrity in PD (Pereira et al., 2009; Zarei et al., 2013). Individuals with PD may also be impaired in gesture perception because of their own motor difficulty, as there is evidence for a common coding system between perception and action (Bidet-Ildes, Chauvin, & Coello, 2010; Calvo-Merino, Glaser, Grèzes, Passingham, & Haggard, 2005; Serino et al., 2009).

Only a handful of studies to date have investigated gesture perception and comprehension in PD, with some finding intact performance (Bonivento, Rumiati, Biasutti, & Humphreys, 2013; Leiguarda et al., 1997) and one showing impaired implicit processing of non-social gestures (Klooster, Cook, Uc, & Duff, 2015). In a neuroimaging study (Lotze et al., 2008), PD participants made significantly more errors in recognizing emotional gestures than did healthy control participants, though recognition of non-emotional (object-oriented) gestures was intact. In the PD group, there was reduced activation across several visual-motor regions, such as STS, when contrasting the emotional vs. non-emotional gestures. This study provides the strongest evidence to date for impaired gesture perception in PD and its association with neural regions implicated in biological motion perception such as the STS.

One major weakness of these studies is that gesture stimuli are often videos of the hand or full body, which makes it difficult to ascertain to what extent individuals with PD are relying on motion cues to render their decision. The presence of morphological cues from the face and body confounds examination of gesture perception specifically from biological motion, such as in the study by Lotze et al. (2008). It is therefore unknown to what extent the PD deficit in this study was specifically related to motion cues. This is an important question because in visually degraded or noisy conditions when morphological features are obscured or ambiguous, individuals with PD may need to rely predominantly on biological motion for accurate social perception. Even when morphology and motion cues provide social information, understanding potential difficulties in perceiving social information from biological motion could be useful in creating targeted rehabilitation programs for individuals with PD, such as training to improve motion perception in addition to improving other forms of social cognition.

In the present study, we investigated gesture perception and comprehension in PD using point-light stimuli to represent biological motion, where the only visual cues are points of light on the major joints of the body. Such stimuli are commonly used to isolate visual information to motion and reliably convey actions and emotions (Clarke, Bradshaw, Field, Hampson, & Rose, 2005; Dittrich, 1993; Johansson, 1973). The use of point-light stimuli allowed us to investigate if individuals with PD are impaired in perceiving gestures specifically from visual motion. We predicted that the PD group would perform more poorly than the control group in discriminating between communicative and non-communicative gestures, and in accurately describing communicative gestures.

We also conducted exploratory analyses to investigate whether gender would affect the performance of PD individuals on gesture perception. Gender differences exist in PD with regards to disease symptoms (I. N. Miller & Cronin-Golomb, 2010). Men with PD perform more poorly on tasks of social cognition (e.g., emotion recognition; Clark et al., 2008 and 2010) and have greater difficulty with social communication (Lubomski, Rushworth, Lee, Bertram, & Williams, 2014). In healthy adults, women perform better on emotion recognition tasks than men (Thompson & Voyer, 2014). When interpreting emotions from ambiguous audiovisual information (facial expressions and speech), men rely more on linguistic cues whereas women rely more on extra-linguistic, nonverbal cues (Marquardt, Levitt, Sherrard, & Cannito, 2014). We therefore predicted that men with PD would have particular difficulty in gesture perception.

Method

Participants

The study included 23 individuals with PD and 24 normal control adults (NC). Participants were recruited through the Parkinson's Disease and Movement Disorders Clinic at Boston Medical Center, Boston University's Sargent College of Health and Rehabilitation Sciences, the Michael J. Fox Foundation's Clinical Trial Finder website, and research talks at local PD support groups. PD and NC participants were matched for age, education level, and male:female ratio (see Table 1). All were native speakers of English or completed high school in English, had at least 12 years of education, and lived at home. PD participants

were included if they met clinical criteria for mild to moderate idiopathic PD (Hoehn & Yahr Stage 1–3, U.K. Parkinson's Disease Society Brain Bank diagnostic criteria; Hughes, Daniel, Kilford, & Lees, 1992). Motor disability was quantified using the Unified Parkinson's Disease Rating Scale (UPDRS) Motor subscale. They were in the “on” state during testing. Levodopa-equivalent-dosage (LED; mg/day) was calculated using a standardized formula (Tomlinson et al., 2010). One individual with PD was not taking any medications.

Exclusion criteria for both groups included serious chronic medical, neurologic (other than PD), or psychiatric illness; mental retardation; history of intracranial surgery; history of traumatic brain injury with loss of consciousness greater than a few seconds; current or previous substance or alcohol abuse; and diagnosis of eye disease. Use of antidepressants and anxiolytics was permitted in the PD group only, because of the frequent use of these medications in this population. Use of other psychoactive medications in either group was grounds for exclusion.

All procedures were approved by the Boston University Institutional Review Board in accordance with the Helsinki Declaration. Participants signed an informed consent form prior to beginning the study.

Screening Measures and Questionnaires

Dementia was screened for using the Columbia-Modified Mini Mental State Examination (MMSE) and all participants scored above 27/30 (conversion to standard MMSE scores). The Geriatric Depression Scale (GDS) and the Beck Anxiety Inventory (BAI) were used to assess symptoms of depression and anxiety, respectively. Participants had corrected binocular visual acuity equal to or greater than 20/40 (logarithm mean angle of resolution, logMAR = 0.3; Lighthouse Near Visual Acuity Test at 16 inches). Contrast sensitivity was determined using the Functional Acuity Contrast Test (FACT) at a distance of 16 inches.

Gesture Perception Task

Participants viewed point-light human figures that conveyed gestures made with the arms, hands, and fingers. The stimuli were created in a motion capture laboratory at Dalhousie University (Zaini, Fawcett, White, & Newman, 2013) and were composed of 23 white point-lights on a black background (lights placed on a male actor's head, shoulders, elbows, wrists, all 10 finger tips, hips, knees, and ankles). The actor faced the viewer while performing the gestures. The point-lights depicted gestures that were either (a) *communicative* – emblems or intransitive gestures that are meant to convey or exchange information with another person and that have commonly accepted meanings (e.g., a thumbs-up gesture to signal “good job”) (McNeill, 1985, 1992); or (b) *non-communicative* – instrumental pantomimes or transitive gestures of object-oriented actions that do not convey information to another person (e.g., leaning over and moving hands back and forth in a “sweeping the floor” gesture) (examples in Figure 1).

These point-light stimuli were validated on a group of 20 young adults by Zaini et al. (2013). Briefly, this group of young adults was asked to verbally identify the gestures. The entropy statistic H was calculated to determine participant agreement; stimuli that did not have high

agreement were excluded from the corpus. We chose 25 communicative and 25 non-communicative gestures (see Table 2) from the corpus that were highly recognized by the research participants from the validation study and that were suitable to present to older adults in this study. Some stimuli we chose elicited relatively poorer recognition in the validation study, but were selected because they appeared particularly relevant to our sample of older adults (e.g., sewing gesture). We did not include stimuli with an obvious cultural component (e.g., signing the cross).

The 50 point-light gestures were presented to participants in a random order. The stimuli ranged in duration from 1.85 to 5 seconds. After viewing each stimulus, participants had two tasks: (1) make a forced-choice decision as to whether the stimulus depicted a communicative or non-communicative gesture (Gesture Discrimination Task); and (2) provide a short verbal description of the gesture (Gesture Description Task). Participants were allowed as much time as needed to respond, and encouraged to guess if necessary, but were not allowed to replay a video. Although the instructions stated to first discriminate and then describe the gesture, some participants first described the gesture and then provided their discrimination response.

The Gesture Discrimination Task assessed whether patients could identify communicative and non-communicative gestures in a forced-choice format, while the Gesture Description Task assessed whether patients could infer, retrieve, and verbalize the correct intention of the gesture. A participant's response to a stimulus on the Gesture Discrimination task was scored independently of his or her response on the Gesture Description task.

At the beginning of the test, participants were provided with detailed instructions as well as definitions and examples of what constituted communicative and non-communicative gestures. They were instructed to respond "communicative" if they believed that the gesture was communicating information to another person who was not shown in the video, and "non-communicative" if the gesture was not communicating information to another person and instead depicted an action involving an object (that was not shown). They were then asked to provide a short verbal description of the action or gesture. Participants answered verbally and the responses were recorded by the examiner. Six practice trials were provided using stimuli that were not included in the experiment. In the practice trials only, participants were given feedback on their responses.

Gesture Perception Task—Scoring

On the Gesture Discrimination task, participants were awarded one point for each stimulus they correctly identified as communicative or non-communicative. Percent correct was calculated for each gesture type. On the Gesture Description task, correct responses were awarded one point, and were defined as follows: (1) exact wording or paraphrasing of the stimulus, based on the responses provided by Zaini et al. (2013); (2) lengthy descriptions of the correct answer (e.g., "he's having lunch" was considered a correct response for "eating"); (3) synonyms of the correct answer (e.g., "admonishing" was considered a correct response for "shaming"); (4) for non-communicative gestures that involved an object, replacement with another appropriate object or the generic name of that object (e.g., "drinking a liquid", "drinking water", and "drinking a beer" were all acceptable responses

for “drinking”). Of participants’ correct responses for communicative gestures, 37% fell under response type (1), 51% fell under response type (2), and 12% fell under response type (3). Of participants’ correct responses for non-communicative gestures, 68% fell under response type (1), 19% fell under response type (2), 7% fell under response type (3), and 6% fell under response type (4). Responses in which the participant only described the action without demonstrating an understanding of the meaning of the gesture were scored as incorrect (e.g., “he raised his hand to his head” was not a correct response for “saluting”).

A trained research assistant who was blind to participants’ group status scored the responses. An additional research staff member checked this initial scoring for accuracy. Discrepancies (i.e., a disagreement in scoring or a scoring error) were resolved by discussion. There was agreement between the two scorers on the majority of responses across participants (communicative gestures: 91% agreement of initial scoring decision; non-communicative gestures: 96% agreement of initial scoring decision). Any response that both scorers deemed ambiguous was further judged for correctness by agreement of 6 or more of 8 independent scorers, who were blind to group. This resulted in an additional 10 responses being marked as correct.

Procedure

Administration of screening measures, questionnaires, vision tests, and perception tasks was completed in a quiet testing room. The gesture stimuli were QuickTime movie files (640 x 480 pixels, 24 frames per second) that were converted to Audio Video Interleaved (.avi) format and displayed on a CRT monitor (Mitsubishi Diamond Pro 21 inch monitor with 160 Hz max refresh rate). All stimuli were presented using either MatLab 2009a (MathWorks, Natick, MA) and Psychophysics Toolbox version 3.0 (Brainard, 1997; Kleiner, Brainard, & Pelli, 2007; Pelli, 1997), or using SuperLab 5.0 Presentation Software (Cedrus, USA). Participants sat in a comfortable, adjustable seat and were given frequent breaks as needed.

Statistical Analyses

Group differences on the Gesture Discrimination Task and Gesture Description Task were analyzed separately using mixed design analysis of variance (ANOVA) with Group (PD, NC) as the between-subjects variable and Gesture Type (communicative, non-communicative) as the within-subjects variable. Results of all ANOVAs are reported in Table 3 and mean (standard deviation) accuracy in Table 4. Post-hoc analysis was conducted using independent samples *t*-tests. Percent correct was used as the dependent variable.

For simple main effects and interaction effects in ANOVA, we report effect size using η^2 , the proportion of the total variance in the data that is accounted for by that effect, where .01 is a small effect, .06 is a medium effect, and .14 is a large effect. For post-hoc and planned comparisons of two means, we report effect size using Cohen’s *d*, where .2 is a small effect, .5 is a medium effect, and .8 is a large effect. The pooled standard deviation was used as the standardizer (denominator) for calculating Cohen’s *d*.

Results

Demographics and Clinical Measures

PD and NC participants did not differ significantly in age, education, visual acuity, general cognitive status (MMSE), symptoms of depression (GDS), or symptoms of anxiety (BAI) (all F s < 2.52 , p s $> .05$). There was no difference in male:female ratio between groups ($\chi^2 = .02$, $p > .05$) nor did men and women differ in age, education, acuity, and symptoms of depression or anxiety (all F s < 2.49 , p s $> .05$).

Group differences in contrast sensitivity (FACT chart) were determined using a 2x5 mixed design ANOVA with a between subjects factor of Group (PD, NC) and within subjects factor of Spatial Frequency (1.5, 3, 6, 12, and 18 cycles/degree). There was a main effect of Spatial Frequency ($F(4,172) = 236.79$, $p < .01$, $\eta^2 = .84$) and a main effect of Group ($F(1,43) = 8.58$, $p < .01$, $\eta^2 = .17$). PD had poorer contrast sensitivity than NC regardless of spatial frequency ($p < .01$, $d = .86$). There was no Group x Spatial Frequency interaction ($F(4,172) = 1.71$, $p > .05$, $\eta^2 = .01$). There was a Group x Gender x Spatial Frequency interaction ($F(4,164) = 2.64$, $p < .05$, $\eta^2 = .01$). PD men had poorer contrast sensitivity than NC men at 6 and 12 cycles/degree ($t(18)$ s > 2.27 , p s $< .05$, d s > 1.07). PD women had poorer contrast sensitivity than NC women at 3 and 18 cycles/degree ($t(25)$ s > 2.80 , p s $< .01$, d s > 1.11). There was no significant difference in contrast sensitivity between PD men and PD women.

Gesture Discrimination Task

Results are displayed in Figure 2. As shown by the 95% confidence intervals (error bars) of the means in Figure 2, both PD and NC performed significantly above chance level (50%). There was a main effect of Gesture Type, where participants demonstrated better accuracy on non-communicative gestures than on communicative gestures ($p < .05$, $d = .67$). There was no significant main effect of Group or Group x Gesture Type interaction.

Gesture Description Task

Results are displayed in Figure 3. There was a main effect of Gesture Type, with all participants performing better on non-communicative gesture trials than on communicative gesture trials ($p < .01$, $d = 1.09$). There were trends towards a main effect of Group and a Group x Gesture Type interaction. To explore this trend, we conducted an independent samples t -test, analyzing PD-NC differences separately for communicative and non-communicative gestures in the Gesture Description Task. Whereas there was no significant PD-NC difference for communicative gestures ($t(45) = .59$, $p > .05$, $d = .17$), PD performed significantly more poorly than NC (large effect) on the non-communicative gesture trials ($t(45) = 2.82$, $p < .01$, $d = .82$).

Effect of Gender on Gesture Discrimination Task and Gesture Description Task

To investigate the possible effect of gender on performance, we conducted 2 x 2 x 2 ANOVAs separately for the Gesture Discrimination Task and the Gesture Description Task. The between-subjects factors were Group (PD, NC) and Gender (Men, Women) and the within-subjects factor was Gesture Type (communicative, non-communicative). Results on the Gesture Discrimination Task are shown in Figure 4. As shown by the 95% confidence

intervals (error bars) of the means in Figure 4, both PD and NC men and women performed significantly above chance (50%). There was a significant Group x Gender interaction. Regardless of gesture type, men with PD had poorer accuracy than women with PD ($t(12) = 1.97, p = .07, d = .86$) and NC men ($t(12) = 2.15, p = .05, d = .96$) at a trend level (large effect). Women with PD did not differ from NC women ($t(25) = .59, p > .05, d = .23$). NC men and women did not differ ($t(22) = .97, p > .05, d = .40$). There was no significant Gesture Type x Gender interaction or Group x Gesture Type x Gender interaction.

On the Gesture Description Task, there was a significant Group x Gender interaction, shown in Figure 5. Regardless of gesture type, men with PD had poorer accuracy than women with PD ($t(21) = 1.87, p = .08, d = .76$) at a trend level (medium effect), and significantly poorer accuracy than NC men ($t(18) = 2.21, p < .05, d = .99$). Women with PD did not differ from NC women ($t(25) = .05, p > .05, d = .02$). NC men and women did not differ ($t(22) = .84, p > .05, d = .34$). There was no significant Gesture Type x Gender interaction or Group x Gesture Type x Gender interaction.

Correlation with Contrast Sensitivity

Because of the main effect of Group on contrast sensitivity, we explored the relation between gesture perception and contrast sensitivity using Spearman rank-order correlation, with a conservative alpha of .01. In the PD group, contrast sensitivity at 1.5 cycles/degree correlated with better performance in discriminating ($\rho = .64, p = .001$) and describing ($\rho = .60, p = .02$) communicative gestures only. In the NC group, contrast sensitivity at 1.5 cycles/degree correlated with worse performance in describing communicative gestures ($\rho = -.49, p = .01$), and contrast sensitivity at 12 cycles/degree correlated with better performance in discriminating communicative gestures ($\rho = .61, p = .002$). In the sample as a whole, no significant correlations were found between contrast sensitivity at any spatial frequency and performance on the gesture discrimination and gesture description tasks (all $ps < .34, ps > .02$). Given this latter finding, and our quasi-experimental design that precludes analysis of covariance, contrast sensitivity was not used as a covariate in the analyses.

Discussion

This study investigated whether perception of communicative (intransitive, social) and non-communicative (transitive, object-oriented) gestures was impaired in PD along two dimensions: the ability to identify and describe an observed gesture and the ability to discriminate between communicative and non-communicative gestures. The gestures were perceived from point-light biological motion, which restricted visual information to motion cues alone.

Our results supported the hypothesis that PD would demonstrate a deficit in describing gestures from biological motion, though we found this group difference only for non-communicative gestures. We also discovered that gender affected the relation between PD and gesture perception. Our findings are consistent with those of our recent study, in largely the same sample of PD and NC participants, which showed reduced sensitivity to perceiving point-light walking (Jaywant et al., submitted). Here we show that perception of meaningful object-oriented actions from biological motion, beyond simple walking, is also impaired in

PD. Critically, the ability to perceive gestures from biological motion in PD depends on the type of information conveyed by the gesture (communicative or non-communicative) and the gender of the PD observer.

We found that PD participants as a whole had a selective deficit in describing non-communicative gestures. Being able to accurately perceive non-communicative gestures from motion cues is important because, even though some gestures do not have a communicative intent, they allow the observer to determine the action and activity of a potential communication partner, which can guide social interaction. A deficit in non-communicative gesture perception could therefore impact an individual with PD's ability to initiate conversation or accurately and efficiently manage a social interaction. Being able to perceive gestures from motion cues is important in visually degraded conditions where a communication partner's morphological features are ambiguous or occluded, such as may occur in dim lighting, far away distance, inclement weather, or crowded situations (e.g., public transit).

This finding of a selective deficit in perceiving non-communicative gestures was unexpected given previous research that has shown the opposite pattern (i.e., a PD deficit for communicative/emotional gestures but not non-communicative/non-emotional gestures) using standard ("full-light") stimuli (Lotze et al., 2008). One possibility was that our sample had trouble describing object-oriented actions because of their own motor problems induced by PD, as suggested by evidence for a common coding system for perception and action mediated by the mirror neuron system (Iacoboni & Dapretto, 2006). Future research should address the possible link between motor dysfunction and gesture perception in PD.

Another possible explanation for the group difference in performance was that the PD group had worse contrast sensitivity than the NC group. We found correlations between contrast sensitivity and perception of communicative gestures in the PD and NC groups, which did not differ on perception of this type of gesture, but no correlations between contrast sensitivity and non-communicative gestures, for which the PD group performed more poorly than the NC group. Furthermore, both communicative and non-communicative point-light stimuli had the same contrast, but the PD group performed more poorly than NC in describing only the non-communicative gestures. It is therefore unlikely that contrast sensitivity was driving our findings.

A deficit in perceiving non-communicative gestures, but not communicative gestures, may be partially accounted for by the type of stimuli presented in our study. We employed point-light stimuli, which restrict visual information to motion, and found those with PD to be impaired at describing non-communicative gestures. In other studies that have found differing results, the stimuli were full-light videos that included morphological cues such as facial expression and posture (Leiguarda et al., 1997; Lotze et al., 2008). It may be that difficulty perceiving communicative gestures arises primarily from impairment in decoding morphological features, or integrating morphology and motion information. Moreover, the emotional valence of our communicative gestures was unknown and some gestures (e.g., "call me," "hello") were not characterized by a specific emotion. Differences in the emotional content of our gestures relative to those in other studies may also explain the

differences in results. That is, because PD is associated with deficits in emotional processing, gesture perception from biological motion may be more impaired when an emotion has to be decoded. The ability of individuals with PD to perceive emotional gestures from biological motion is a topic for future study.

Differences between studies may also reflect differences in sample size and characteristics. Our PD group was composed of 23 participants, while the sample of Lotze et al. (2008) had only eight participants; hence our study had more power to detect group differences. Relative to their sample, our PD group had shorter disease duration (4.8 years vs. 12.8 years), less severe motor symptoms (UPDRS 33 vs. 38), and a milder range of disease stage (0 out of 23 vs. 2 out of 8 participants at Hoehn & Yahr stage 4). It is possible that our sample was only beginning to show impairments, and that replication of the study with a PD group at more advanced stages of the disease may yield differences in regard to the interaction between PD and gesture description for communicative and non-communicative gestures. Future studies should also investigate gesture perception from point-light and full-light stimuli in the same PD sample, to better understand how motion cues alone and in combination with morphological cues affect perception.

A secondary goal of the current study was to explore the possible moderating effect of gender on PD gesture perception. There is accumulating evidence that disease profiles can differ in men and women with PD, possibly due to a neuro-protective effect of estrogen in women (I. N. Miller & Cronin-Golomb, 2010). Moreover, emotion recognition and social communication is worse in men than women with PD (Clark et al., 2008; Lubomski et al., 2014). We found that men with PD performed more poorly than women with PD and NC men in discriminating between communicative and non-communicative gestures, and in verbally describing both communicative and non-communicative gestures. This finding is consistent with prior research and underscores the importance of looking at subgroup of individuals with PD.

Replication of this gender effect on biological motion perception with a larger sample size is warranted. Some of the differences we observed between men and women were only at a trend level, and confidence intervals were large (e.g., Figure 5). Additionally, while our PD and NC groups were matched for age, it is possible that deficits in gesture perception may manifest as an interaction between age, gender, and disease burden in PD, as social perception changes with age (Isaacowitz et al., 2007; Marquardt et al., 2014). A larger sample would allow analysis on the interaction of age and gender in gesture perception in PD.

We observed that both PD and NC were able to more accurately identify non-communicative gestures than communicative gestures across tasks. It is possible that participants demonstrated better accuracy on the non-communicative trials because object-oriented gestures such as “throwing a ball” and “casting a fishing rod” may have concrete and relatively unambiguous stored representations that are readily accessed when perceiving the gesture (Bonivento et al., 2013). By contrast, a number of social and cultural factors play into how humans interact with and communicate with one another, which may have resulted in greater ambiguity of our communicative gestures. Additionally, the lack of an observed

partner for communicative gesture trials may have contributed to the observed lower performance on these trials by removing an important context for decoding the meaning of social gestures.

In summary, the present study showed that as a group, those with PD are impaired relative to NC in inferring and describing the meaning of non-communicative gestures, but are comparable to NC in describing communicative gestures. Men with PD, however, have difficulty in understanding not only the actions of others (non-communicative gestures), but also others' communicative gestures in interpersonal exchanges. Our results add to a growing body of literature that indicates difficulty in perceiving social cues in PD. We argue for the importance of assessing dynamic visual perception in PD, which may reveal different deficits than those elicited by conventional tasks that employ static visual stimuli.

Our results also have implications for rehabilitation in PD. If future research determines that a biological motion perception deficit has functional ramifications in ecologically valid settings for individuals with PD, then improving biological motion would be an important rehabilitation goal. Perceptual training improves biological motion in healthy young and older adults (Grossman, Blake, & Kim, 2004; Legault & Faubert, 2012), and the possibility exists that training may also enhance social perception from biological motion in PD. Because we found that gesture perception was different in men and women, rehabilitation approaches that aim to improve social cognition and social engagement in PD may require tailoring the rehabilitation approach to specific subgroups with the disease.

Acknowledgments

This work was supported by the National Institute of Neurological Disorders and Stroke, including a Ruth L. Kirschstein National Research Service Award to AJ (grant number F31 NS078919) and an R01 grant to ACG (grant number R01 NS067128). We thank Terry Ellis, Ph.D., and Serge Roy, Sc.D., for help with experimental design, statistical analysis, and manuscript review, and Marie Saint-Hilaire, M.D., Cathi Thomas, R.N., M.S.N., and the Fox Foundation Trial Finder for participant recruitment. We are grateful to members of the Vision & Cognition Laboratory for their assistance in scoring and especially to Valerie Levit, B.A., who also assisted in data organization. We acknowledge the contribution of Aaron Newman, Ph.D., who created the point-light figures stimulus set. The authors of this study have no conflicts of interest to declare.

Figure 1. Example still frames of communicative (a and b) and non-communicative (c and d) point-light gesture videos: a.) “waving hello”; b.) “I’m cold”; c.) “shoveling”; d.) “picking up an object.”

Figure 2. Performance on the Gesture Discrimination Task by Group (Parkinson's disease [PD], normal control [NC]) and Gesture Type (communicative, non-communicative). Error bars represent 95% confidence intervals. PD and NC did not differ in performance. Non-communicative gestures were better recognized than communicative gestures, regardless of group.

Figure 3.

Performance on the Gesture Description Task by Group (Parkinson's disease [PD], normal control [NC]) and Gesture Type (communicative, non-communicative). Error bars represent 95% confidence intervals. PD had poorer accuracy than NC for non-communicative gestures, but not communicative gestures. Non-communicative gestures were easier to describe than communicative gestures regardless of group.

Figure 4. Performance on the Gesture Discrimination Task by Group (Parkinson's disease [PD], normal control [NC]) and Gender (Male, Female), averaged across Gesture Type (communicative, non-communicative). Error bars represent 95% confidence intervals. Men with PD performed worse than women with PD and NC men at a trend level. Women with PD did not differ from NC women. NC men did not differ from NC women.

Figure 5.

Performance on the Gesture Description Task by Group (Parkinson's disease [PD], normal control [NC]) and Gender (Male, Female), averaged across Gesture Type (communicative, non-communicative). Error bars represent 95% confidence intervals. Men with PD performed significantly worse than women with PD and NC men. Women with PD did not differ from NC women. Men and women NC did not differ.

Table 1

Participant Characteristics

Measure	PD (N = 23)	NC (N = 24)	Significance
Age (years)	65.0 (8.0 [51–83])	62.5 (8.6 [45–78])	<i>NS</i>
Education (years)	16.8 (1.7 [13–20])	17.3 (1.8 [12–20])	<i>NS</i>
Men:Women	10:13	10:14	<i>NS</i>
UPDRS Motor Score	19.5 (7.1 [4–36])	--	--
H & Y Stage, median (range)	2 [1–3]	--	--
LED (mg/day)	491 (274 [0–900])	--	--
Acuity (logMAR)	0.07 (0.1 [–0.1, 0.2])	0.03 (0.12 [–0.1, 0.3])	<i>NS</i>
MMSE	28.6 (0.9 [27.24–29.71])	28.9 (0.8 [26.74–29.71])	<i>NS</i>
GDS	6.0 (3.9 [0–15])	4.1 (5.0 [0–19])	<i>NS</i>
BAI	5.2 (5.3 [0–24])	3.1 (3.8 [0–16])	<i>NS</i>
SASS	47.1 (6.2 [36–58])	47.5 (6.8 [33–56])	<i>NS</i>
PDQ-39	34.3 (20.0 [9–87])	--	--

Note. PD = Parkinson's disease; NC = normal control participants. UPDRS = Unified Parkinson's Disease Rating Scale; H & Y = Hoehn & Yahr stage; LED = Levodopa equivalent dosage; logMAR = logarithm of mean angle of resolution; MMSE = Mini-Mental State Examination; GDS = Geriatric Depression Scale; BAI = Beck Anxiety Inventory; SASS = Social Adaptation Self-Evaluation Scale; PDQ-39 = 39-item Parkinson's Disease Questionnaire (quality of life measure). Values presented are means (standard deviations [range]), unless otherwise indicated.

Table 2

List of Communicative and Non-Communicative Gesture Stimuli

Communicative Gestures	Non-Communicative Gestures
Air quotes	Brushing teeth
All done	Buttoning a shirt
Call me	Combing hair
Calm down	Conducting orchestra
Cheering	Drinking water
Clapping	Driving a car
Come here	Drying one's body
Enough	Eating
Good job	Fishing
Can't hear you	Hammering a nail
Hello	Hanging clothes to dry
I can't look	Paddling
I'm cold	Picking up a box
I'm sleepy	Playing guitar
I'm watching you	Playing violin
Offering a drink	Pouring water
Rubbing tummy	Pulling rope
Saluting	Sewing
Shaming	Shooting a basketball
Shhh	Shoveling
Shrug	Stirring
Smelly	Sweeping the floor
Thinking	Swimming
Time out	Throw a snowball
Yawning	Washing hands

Table 3

Results of Statistical Analyses (ANOVA)

Effect	<i>df</i>	<i>F</i>	<i>p</i>	η^2
