Abstract

Purpose—Defining robust criteria for drug activity in preclinical studies allows for fewer animals per treatment group, and potentially allows for inclusion of additional cancer models that more accurately represent genetic diversity and, potentially, allows for tumor sensitivity biomarker identification.

Methods—Using a single mouse design, 32 pediatric xenograft tumor models representing diverse pediatric cancer types (Ewing sarcoma [9], brain [4], rhabdomyosarcoma [10], Wilms tumor [4], and non-CNS rhabdoid tumors [5]) were evaluated for response to a single administration of pegylated-SN38 (PLX038A), a controlled-release PEGylated formulation of SN-38. Endpoints measured were percent tumor regression, and Event Free Survival (EFS). The correlation between response to PLX038A was compared to that for 10 models treated with irinotecan (2.5 mg/kg × 5 days × 2 cycles), using a traditional design (10 mice/group). Correlations between tumor sensitivity, genetic mutations and gene expression were sought. Models showing no disease at week 20 were categorized as 'extreme responders' to PLX038A, whereas those with EFS less than 5 weeks were categorized as 'resistant'.

Results—The activity of PLX038A was evaluable in 31/32 models. PLX038A induced >50% volume regressions in 25 models (78%). Initial tumor volume regression correlated only modestly

This article does not contain any studies with human participants.

with EFS ($r^2 = 0.238$), but sensitivity to PLX038A was better correlated with response to irinotecan when one tumor hypersensitive to PLX038A was omitted ($r^2=0.6844$). Mutations in *53BP1* were observed in 3 of 6 sensitive tumor models compared to none in resistant models (n=6).

Conclusions—This study demonstrates the feasibility of using a single mouse design for assessing the antitumor activity of an agent, while encompassing greater genetic diversity representative of childhood cancers. PLX038A was highly active in most xenograft models, and tumor sensitivity to PLX038A was correlated with sensitivity to irinotecan, validating the single mouse design in identifying agents with the same mechanism of action. Biomarkers that correlated with model sensitivity included wild type *TP53*, or mutant *TP53* but with a mutation in *53BP1*, thus a defect in DNA damage response. These results support the value of the single mouse experimental design.

Introduction

The design of animal experiments to determine antitumor activity of a drug, or drug combination, is largely constrained by statistical considerations regarding the power to detect specific differences between control and treatment groups. This is in part determined by variance within the rate of growth of untreated controls, and the magnitude of the response to be detected. Greater variance between growth of control tumors necessitates increased numbers of animals to yield adequate statistical power, whereas increasing the stringency of response criteria can have the opposite effect on group size. In preclinical studies, growth rates for tumors in treated animals are compared to those in controls, hence one can obtain data to show that treatment gives statistically significant differences (usually $P<0.05$), although statistical significance does not imply a biologically meaningful effect. Tumor progression (>25% increase in tumor volume) on treatment is progressive disease in a clinical setting.

Clinical trial designs tend to use two endpoint criteria, tumor regression and Progression-Free Survival (PFS). Response evaluation criteria in solid tumors (RECIST) sets out rules for evaluating when patients improve (respond), stay the same (stabilize) or worsen (progress)[1]. Statistical differences between an experimental protocol are compared to an historical control arm, or more likely an alternative regimen, standard of care, or physicians choice. One objective of preclinical experiments is to generate data that may accurately translate into the clinic. When considering how to assess antitumor activity when establishing the Pediatric Preclinical Testing Program (PPTP) it was considered that endpoint criteria should be similar between preclinical and clinical experiments [2]. In the ensuing ten years where over 2100 tumor-drug evaluations were undertaken, it became clear that the great majority of drugs had relatively modest activity, or lacked activity, if these criteria were used. However, of greater concern was that using the standard design, based on the need to demonstrate ‘statistical significance’ relatively few models (n=6 to 8) were used to represent a disease state (e.g. neuroblastoma). Genomics studies have revolutionized our understanding of histotype heterogeneity, with many pediatric cancers being classified into multiple subgroups based upon exome sequencing, expression profiles etc.[3–9]. Thus,

within resource constraints, it is reasonable to ask how one resolves the need to represent genetic heterogeneity, with considerations of statistical validity.

In a retrospective analysis of PPTP data that included 83 xenograft models, 67 drugs or biologics having different mechanisms of action, and over 2100 experiments, we found that use of one mouse per treatment group would give the same result as the use of 10 mice (solid tumors) or 8 mice (acute leukemia models) in ~80% of experiments, and if small differences were allowed (partial response vs complete response [PR vs CR], for example) the predictive value of the single mouse approach was ~95% [10].

Using conventional experimental designs, where group size is determined according to the variance in the rate of growth of tumors within a group and statistical endpoint being applied (for example as described in [2]), necessitates use of large numbers of animals if relatively small drug effects are being sought. Thus, with finite resources, this necessarily restricts the number of models of any one cancer type that can be used. In the PPTP 6–8 models were used to represent each disease (e.g. osteosarcoma, neuroblastoma etc.). Clearly, such a small number of models can not accurately represent the genetic/epigenetic diversity of these cancer types. Thus, alternative approaches to preclinical in vivo testing need to be considered. We have proposed use of a ‘single mouse’ experimental design, where each mouse has a different patient derived xenograft, and endpoints are tumor regression and Event-Free Survival (EFS). In this design, there is no control (untreated) tumor. Support for this idea comes from our retrospective study [10] that indicated use of one mouse per treatment group was adequate to identify agents that had activity and those that did not. If we consider control and treatment groups of 10 mice each, the single mouse design potentially allows inclusion of 20 models for every one used in conventional testing experiments.

Thus, the use of the single mouse approach allows for inclusion of more models of each pediatric cancer type, and hence increases the genetic heterogeneity potentially allowing identification of biomarkers of response that can be interrogated in a subsequent clinical trial. For example, assessing the activity of a drug against, say 30 tumors of one type (e.g. 30 medulloblastomas) may identify that drug sensitivity segregates with a particular set of genetic characteristics that may or may not be those shown to subclassify this disease[6,11]. For example, preclinical testing in a large panel of adult melanoma xenografts shows that BRAF mutant models respond to BRAF inhibitors, whereas those with wild type BRAF are less sensitive. Also, use of a larger number of models representative of a histotype may improve the prediction for activity in clinical trials[12].

Although the single mouse approach is supported by the retrospective analysis of PPTP results, it has not been tested prospectively using pediatric cancer models. Here we have tested the feasibility of the single mouse design to prospectively evaluate a long-acting PEGylated SN-38 prodrug, PLX038A, where SN-38 (the active metabolite of irinotecan) is released at a controlled rate [13,14]. PLX038A was selected, as we have extensive recently derived data showing the activity of irinotecan in many of the same models using traditional testing design (10 mice/treatment and control groups); the conjecture being that xenograft models most sensitive to irinotecan would be the most sensitive to PLX038A, and

conversely, tumors less sensitive to irinotecan would be less sensitive to PLX038A (i.e. validation of the ability of the single mouse design to identify an agent where there is already data [from an analog] to indicate activity using conventional testing). Further, irinotecan has significant clinical activity, and is used in several high-risk and relapse protocols for treating childhood solid tumors [15,16]. Other objectives of the study were to determine whether initial tumor volume regression correlated with EFS, and to mine the genomics data on each tumor model to identify potential biomarkers that relate to drug sensitivity.

Methods

The xenograft models used together with limited demographic data, where available, are presented in Table 1. Patient derived xenografts (PDX; rhabdomyosarcomas Rh10, Rh18xe, Rh28, Rh30, Rh30R, Rh36, Rh41, Rh65; Wilms tumors KT5, KT10, KT11, KT13; and rhabdoid tumors KT12, KT14, KT16) and cell line-derived xenografts (Ewing sarcoma lines ES-1, ES-4, ES-6, EW-8, CHLA258, TC-71, SK-NEP-1; rhabdomyosarcomas SMS-CTR and Rh18c) have been described previously [2]. RBD-1 is an atypical teratoid rhabdoid tumor with *SMARCB1* deletion, established as a PDX from a metastatic lung lesion, and the RBD-2 PDX was established from a liver mass. EW-5 and NCH-EWS-1 are Ewing sarcoma PDX's from a paraspinal mass, and lung lesion, respectively. BT-35 and BT-40 brain tumors have been described previously [17]. While BT-40 was originally described as a Juvenile Pilocytic Astrocytoma (JPA) it now resembles an anaplastic astrocytoma in mice. BT-39 was established at recurrence from the same patient as BT-40. S12-6321 was established from a patient with metastatic pleomorphic xanthoastrocytoma [18]. All tumors were used at low passage and authenticated by STR analysis against reference profiles developed by this group. Tumor models were selected for testing without reference to genetic or molecular characteristics, or sensitivity to irinotecan in previous testing.

Evaluation in xenograft models

C.B.17SC scid^{-/-} (C.B-Igh-1b/*IcrTac-Prkdcscid*) female mice (Envigo, Indianapolis, IN) were used to propagate subcutaneously implanted tumors as previously described [2]. All mice were maintained under barrier conditions and experiments were carried out using protocols and conditions approved by the institutional animal care and use committee of UTHSA. Mice were selected when tumors were 200–400 mm³ (Mean 297 ± 34 mm³; range 260–370 mm³). Methods similar to those developed in the Pediatric Preclinical Testing Program (PPTP) were used [2], only for these studies tumor volumes were measured for up to 20 weeks, and regrowth of tumors determined following tumor regression. Endpoints were time to event, defined as tumor growing to 400% of its volume at the initiation of treatment, (event-free survival (EFS), and percent tumor regression. Also recorded was the day where tumor could be detected following complete regression. Complete Regression (CR; defined as tumor volume <40 mm³, the level of detection), and Maintained CR (MCR), was defined as tumor volume <40 mm³ at week 20.

Formulation and treatment

PLX038A was provided as a solution in isotonic acetate buffer (pH 5.0; 143 mM NaCl, 20 mM NaOAc) and contained 8.2 mM SN-38 equivalents (2.1 mM conjugate; 4 equivalent SN-38 molecules/conjugate). Mice received a single administration of 120 $\mu\text{mol/kg}$ (14.6 mL/kg; IP) when tumor volumes were 260–370 mm³. Responses to PLX038A were compared to historical results for 10 xenograft models treated with two cycles of irinotecan (2.5 mg/kg (days 1–5 and 21–25)).

Pharmacokinetics

The synthesis and murine pharmacokinetics of PLX038A and PLX038 have been presented previously[19]. PLX038A was designed to mimic the human pharmacokinetics of PLX038 in mice. This optimization was required to compensate for the faster intrinsic clearance of PEG conjugates in mice. Since the $t_{1/2\beta}$ for PLX038 and PLX038A is 115 hr (human) and 17 hr (mouse), respectively, the rate of SN-38 release must be adjusted accordingly. A single administration of PLX038A (120 $\mu\text{mol/kg}$) was calculated to give adequate exposures of SN-38 over ~ 1 week.

Genomics Analysis

DNA, RNA sequencing, Illumina BeadChip experiments were performed elsewhere [20] as part of the PPTC, according to manufacturer recommended protocols. Briefly, paired-end sequencing was performed on DNA samples by Baylor College of Medicine Human Genome Sequencing Center using Illumina cBot cluster generation system with TruSeq PE Cluster Generation Kits. Whole transcriptome RNA sequencing was performed using total RNA. For both DNA and RNA sequencing data, mouse reads were computationally removed before mutation calling and gene expression quantification. All high-level data have been described and are available on pedcbio portal (<https://pedcbioportal.org/>, under study “Pediatric Preclinical Testing Consortium”). Among the models tested, six were considered responders (MCR at 140 days) and six poor responders (EFS<5 weeks) (Table 2). Mutation data for all 12 models were available and were compared with Fisher’s exact test. Thresholded gene copy number matrix from GISTIC analysis[21] were used to identify genes with differential copy number status between the two groups for the 11 models that had copy number data available (excluding KT5). Fisher’s exact test was applied similarly, followed by multiple testing adjustment with false discovery rate. Gene Set Enrichment Analysis (GSEA) was used to compare pathway expression between the two groups[22] with 5 models in each. KT5 and RBD-1 did not have expression data thus were excluded from this analysis.

Results

Selection of tumor models

The study had two main objectives; firstly to determine the feasibility of the ‘single mouse experimental design, and secondly whether this experimental design would identify tumor models with a spectrum of sensitivities to PLX038A that could reveal molecular characteristics associated with intrinsic sensitivity or resistance. Thus, models were selected

where there was no prior data with irinotecan. However, as an approach to validating the single mouse experimental design, we included 11 models where there was recently derived data for single agent irinotecan, but using conventional testing (i.e. 10 mice per treatment group). The underlying rationale was that if the 'single mouse' data was valid there would be a correlation between model responsiveness to PLX038A with model responsiveness to irinotecan, a drug which has the same mechanism of action. Models used were selected independent of any molecular features. Characteristics of the 32 xenograft models are summarized in Table 1.

Evaluation of PLX038A

PLX038A was administered one time at a dose of 120 $\mu\text{mol/kg}$ by intraperitoneal injection. Volume of tumors was determined on the day of treatment, and at 7 day intervals for a planned 20 weeks. There was one death, the mouse bearing Rh28 tumor died at day 21, probably not drug related. All data for Rh28 (both PLX038A and for irinotecan has been excluded from analysis). Growth curves for each of the remaining 30 xenograft models are shown in the spider plot, Fig.1. Only two models progressed without an initial shrinkage of volume, S12-6321 and Rh10. For tumors where PLX038A induced volume regression, the nadir occurred between day 7 and day 28 following drug administration (median day 7). Thirteen models regressed to below the level of detection ($\sim 40 \text{ mm}^3$; 100% regression), with 12 additional models meeting criteria for Partial Response ($\sim 50\%$ volume regression but $>40 \text{ mm}^3$), as shown in the 'waterfall' plot, Fig. 2A. Six models showed no disease at 20 weeks (Rh36, EW8, KT5, KT11, KT12 and TC-71). At week 20, KT16 xenografts were measurable, but had not reached event at time of terminating the experiment (week 20), shown in the 'swimmer plot', Fig. 2B. There were 8 models where EFS was <5 weeks (ES1, ES4, CHLA258, Rh10, Rh30, Rh41, RBD-1 and S12-6321).

Endpoint criteria: Tumor regression vs EFS

Clinical criteria used in RECIST assessment uses tumor regression and time to event as indicative of antitumor activity of an agent/regimen. Clearly, a single administration of PLX038A was effective at causing regression of most tumor models. However, how relevant initial regression is to outcome (EFS) is less clear ($R^2 = 0.2293$). The relationship between initial tumor regression and EFS is shown in Fig. 2C. Tumors that had the greatest regression (i.e. 100%) tended to have the greatest EFS, however, the relationship is complex with some models regressing completely, but recurring rapidly and having relatively short EFS. For 13 tumors that regressed below the level of detection, the range of EFS was from 38 to >140 days, and time to first detection of tumor following CR ranged from 14 to >140 days. For eight xenograft models that had CR but recurred, the time to event from the first detection of recurrent tumor ranged from 9 days (SMS-CTR) to 46 days KT10, (median 25 days), indicating a range of regrowth rates, independent of the initial response to PLX038A.

Tumor sensitivity to PLX038A vs irinotecan

PLX038A is a controlled release form of SN-38, the active metabolite of irinotecan, hence both agents have the same mechanism of action, although very different pharmacokinetics[19] We therefore sought to determine whether there was a correlation between the response to each agent within the panel of tumors used for the single mouse

experiment, and in a subset of 10 tumor models where evaluation of irinotecan used conventional testing (10 mice per treatment group). In these studies, irinotecan had been administered at 2.5 mg/kg daily for 5 days, with the cycle repeated at day 21. This dose of irinotecan generates SN-38 exposures relevant to exposure in children administered 50 mg/m² daily for 5 days in each cycle of treatment. As shown in Fig.3A, there is a correlation between the event free survival for irinotecan [EFS(IRN)] and that induced by PLX038A [EFS(PLX038A)], however, the relationship is somewhat obscured by the very high EFS induced by PLX038A in the KT11 (Wilms tumor) model. Removing the KT11 ‘outlier’ improved the correlation coefficient (Fig. 3B; $r^2=0.6844$).

Molecular correlates with sensitivity

The ‘single mouse’ experimental approach potentially offers an advantage of allowing evaluation of a drug against a large panel of models within any particular cancer histology, or between histology’s, facilitating the potential to identify ‘extreme responders’ that may be valuable in identifying biomarkers of drug sensitivity or resistance. Within the panel of xenografts, 6 models had EFS >140 days (exceptional responders) and conversely, 6 models where EFS was less than 5 weeks (intrinsically resistant models). We did not observe any gene that demonstrated significant copy number differences between the two groups. However, we found p53 binding protein 1 (*53BP1*) nonsynonymous mutations (two missense and one frame-shift) in 3 of the 6 models that remained in CR at day 140, compared to none in the six tumors with an EFS less than 5 weeks (P value 0.18, Fisher’s exact test; Table 2). Among the three mutants, two (EW8 and TC-71) have mutated *TP53* whereas *TP53* is wild type in 4 models (Rh36, KT5, KT11, KT12). The other two top differentially mutated genes were NPHP4 and HMCN1, both had mutations in three responder cases but none in six resistant models (Fig. 4)

We next compared gene expression of resistant and sensitive models. KT5 from the sensitive group and RBD-1 from the resistant group were dropped due to lack of expression data. Gene Set Enrichment Analysis (GSEA) revealed DNA mismatch repair and replication pathways were up regulated in the resistant group with borderline statistical significance (nominal p values 0.08 and 0.15, respectively) (Supplementary Fig.1), corroborating the observation from mutation data that DNA damage response might be a marker for responses to PLX038A.

There were 9 models where PLX038A induced a CR, but where tumors recurred within the 120 day period of observation. Of these only two (SMS-CTR[23], SKNEP-1) have mutant *TP53*, SKNEP-1 also has a potentially deleterious mutation in *FANCA* (M415I). SMS-CTR was not sequenced as part of the PPTC effort. The PPTC status for SMS-CTR has not been determined. The other 7 models have wild type *TP53*

The drug transporters, *ABCB1*, that encodes P-glycoprotein, and *ABCG2*, that encodes BCRP, have both been implicated in resistance to camptothecin drugs [24,25]. Hence, it was of interest to determine whether the levels of expression of these transporters correlated with intrinsic sensitivity or resistance of the tumor models to PLX038A. Expression (mRNA) of these transporters was available for 14 models (Table 2) from the Pediatric Preclinical Testing Consortium (PPTC) database: <https://pedcbiportal.org>[26]. Of interest, with one

exception (S12–6321) expression of both transporters was very low or not detected, irrespective of the sensitivity of the tumor model to PLX038A. For *ABCB1* levels ranged from 0.00 – 0.322 FPKM and for *ABCG2* from 0.00516 – 0.6387 FPKM. In contrast for S12–6321, mRNA levels for *ABCB1* and *ABCB2* were 27.637 FPKM and 3.940 FPKM, respectively.

Discussion

Compared to adult cancers, most pediatric malignancies have very few coding mutations[27]. However, genomic and other molecular profiling has revealed the molecular heterogeneity of many pediatric cancers. Thus, while the mutation load for pediatric cancers is low in terms of coding mutations per Mb, pediatric cancers are driven by a range of molecular aberrations, and it is estimated that nearly 50% harbor a potentially druggable event[27,28]. For neuroblastoma, a subset of patients have *ALK* mutations that drive the genesis of disease that can be targeted by *ALK* inhibitors [29,30], and mutations in the *RAS* pathway are more frequent at relapse following chemotherapy [31]. For pediatric brain tumors, medulloblastoma can be classed into four main subgroups based upon molecular characterization [6]. One subgroup is characterized by activation of the sonic hedgehog pathway, and some patients have benefitted from treatment with smoothened inhibitors, however not all patients respond [32]. Low-grade glioma (LGG), the most frequent brain tumor in children, is characterized by aberrant *BRAF* signaling, and drugs such as selumetinib or dabrafenib have significant clinical activity [33–35]. However, in the phase II trial of selumetinib, while very few patients with either BRAF-driven LGG or NF1-driven neurofibromatosis progressed on treatment, only 40% achieved criteria for partial response. Hence, even with druggable aberrations there is a diversity of responses that may be conferred by additional mutations or epigenetic changes that are currently not understood. Other frequently occurring genetic changes are anaplasia and *TP53* mutations mark high-risk Wilms tumors [36,37] and *RAS* mutations characterize most of the high-risk embryonal rhabdomyosarcomas [3]. Consequently, at a preclinical level, to adequately represent any clinical entity with reasonable expectation of including its genetic diversity requires generation of many preclinical models.

The experience in adult oncology trials of BRAF or MEK inhibitors in BRAF-mutant melanoma or colon carcinoma, demonstrates that factors other than the driving mutation may influence response to therapy [38,39]. Hence, accurately modeling these diseases may be valuable in identifying effective therapeutic combinations, or molecular characteristics that accurately predict patient response to therapeutics. However, to model the heterogeneity of any clinical disease will require establishment of adequate models, and an experimental design that can accommodate testing. The number of models required to represent a clinical entity will be dependent on the genetic heterogeneity, and the NCI supported PDXNet is an attempt to generate and characterize a large number of patient derived xenografts, organoid and 3D culture lines (<https://www.pdxnetwork.org>). For pediatric cancers that lack the genetic instability that characterizes many adult malignancies, the numbers of models to represent a disease entity may be smaller, although it is important to model tumor at diagnosis and also relapse.

Recent changes in regulatory statutes under the Research to Accelerate Cures and Equity for Children Act (RACE for Children Act), part of the FDA Reauthorization Act (FDARA), requires FDA to develop a list of molecular targets and molecular targets of new drugs and biologics in development, that are determined to be substantially relevant to the growth and progression of pediatric cancer, and that may trigger the requirement for pediatric investigations. The intent is to engage Pharma in pediatric testing at an earlier stage in drug development (<https://www.fda.gov/about-fda/oncology-center-excellence/pediatric-oncology>). As discussed above, all tumors having a similar molecular characteristic (e.g. BRAFV600E or ALK mutation) do not respond equally, and this was clearly demonstrated in the recent phase II evaluation of the MEK inhibitor, selumetinib, in pediatric low-grade glioma[35]. Thus, many PDX's may be required to accurately recapitulate the clinical heterogeneity/drug responsiveness in diseases that exhibit the characteristics identified by FDA. Testing using conventional experimental designs will undoubtedly strain current testing resources, hence the use of the single mouse design, presented here, offers one potential solution.

Researchers at Novartis first proposed using multiple models of melanoma in individual mice as a preclinical approach to simulating clinical diversity[12]. Our retrospective analysis of 10 years of screening for the PPTP indicated that with a few exceptions, models would give similar data whether one or 10 mice per treatment group (for solid tumors or 8 mice per treatment group for leukemias) were used[10]. In this retrospective study, the single mouse accurately predicted group median response in 78% of experiments, and if one allowed a deviation of one response classification the prediction success was ~95%.

To test the feasibility and validity of the single mouse experimental design we prospectively evaluated a PEGylated-SN38 polymer that releases SN-38 at a controlled rate and potentially has greater selectivity through enhanced permeability and retention (EPR) properties [40,41]. The single mouse data was compared to a data set derived using 10 mice per group that evaluated irinotecan (2.5 mg/kg daily $\times$ 5 with treatment repeated at day 21–25) in a subset of models common to both studies. The antitumor activity of both agents is via SN-38 generated poisoning of topoisomerase I, and generation of DNA single and double strand breaks [42,43], thus it was anticipated that there would be a correlation between responses of tumors to both agents, if the single mouse design was accurate. However, as the dosing or exposures to irinotecan were different from PLX038A, it was not anticipated that the results from the two agents would be the same in terms of tumor regression or EFS. We compared 10 models where there was data for irinotecan and PLX038A. Only one tumor model was an outlier (KT11), in that it was far more sensitive to PLX038A than to irinotecan. By omitting KT11 from the analysis, the relationship between EFS induced by either drug improved ($r^2=0.6844$).

Camptothecin-based topoisomerase I poisons are effective in treatment of some pediatric sarcomas[15,44], Wilms tumor [45] and other childhood malignancies[46] alone, or in combination with other cytotoxic agents[47,15,44,48], thus the marked antitumor activity of PLX038A was anticipated. The pediatric cancer models used in this study were highly volume responsive to PLX038A, hence this gave an opportunity to determine whether initial response, in terms of tumor regression, correlated with EFS. Put another way, could initial

volume response be used to predict outcome (EFS). Although there is a relationship it is relatively poor, with EFS ranging from 38->140 days for tumors that initially regressed below the volume for detection. This discordance does not appear to be caused by the intrinsic rate of growth of each tumor model, based on EFS times for control tumors in the irinotecan cohort. This raises the question as to which endpoint is most valuable to use in preclinical studies. Clearly, with these volume-responsive tumor models, there is a poor relationship between volume regression and EFS, that is largely independent of tumor growth rate. This may be a consequence of inadequate sensitivity for tumor measurements, as volume measurements do not accurately reflect log cell kill. We have defined EFS as the time at which a tumor reaches 4-fold the volume at the beginning of treatment. This metric can be used whether a tumor regresses or progresses on treatment. An alternative would be to assess time to progression (PFS; i.e. the day when tumor becomes measurable) for tumors where there is CR of disease following treatment. However, the advantage of EFS over PFS is that with EFS there is a period for continued tumor growth measurement that gives confidence that this is tumor recurrence, and not detection of some fibrotic tissue at the site of the original tumor. Determining EFS is also valuable for calculating log cell kill induced by treatment [49], although the single mouse experimental design does not have a 'control' from which to calculate growth rate. However, for models that have consistent growth characteristics, growth rates from historical cohorts may prove adequate.

The single mouse experimental design allows for a large number of tumors to be evaluated, hence offers an opportunity to relate molecular features in characterized tumor models with drug sensitivity. In the current study, we used baseline genomic and expression profiles derived from PDX models that were derived at different stages of disease and treatment (diagnosis, recurrence, relapse) sequenced as part of the Pediatric Preclinical Testing Consortium (PPTC). Thus, in these tumors, mutations and gene expression profiles represent those in the control situation for the current therapeutic study (i.e. these data were derived before PLX038A or irinotecan treatment in mice). We were able to identify six xenograft models where EFS was less than 5 weeks (intrinsically resistant) and six exceptional responders (EFS >140 days) using the uniform clinical end points, and eventually compared tumors from ten models for genomic correlates with response to PLX038A. While the number was still too small to pinpoint the molecular feature associated with drug sensitivity, our results suggested the mouse models we used can recapitulate drug response phenotypes from histology or even other topoisomerase inhibitors evidenced by the identification of genes implicated in driving distinct responses to this class of agents.

In this study we used models representing several histology's (sarcoma, brain tumors, Wilms/rhabdoid) to demonstrate the feasibility of conducting single mouse studies. We speculate that the single mouse model design is a key as it allows for the inclusion of tumors with different histology thus effectively minimizes confounding tissue effects. Alternatively, conducting such studies utilizing, say, thirty RAS-mutant embryonal rhabdomyosarcomas may reveal a range of sensitivities to MAPK inhibitors, and allow a greater understanding of associated genetic/epigenetic change that correlate with tumor sensitivity. Results presented here raise a testable hypothesis that p53-binding protein 1 (*53BP1*) inactivating mutations are a useful biomarker for responses to PLX038A. In support of this contention it is known that 53BP1 is involved in hyperphosphorylation of replication protein A (RPA2) following DNA

damage, and inhibition of 53BP1 function can sensitize cells to topoisomerase I poisons such as camptothecin[50]. Further investigation of 53BP1-mediated DNA damage repair and PLX038A induced cell death may provide new insights into how these two pathways are interlinked and how this interaction can be exploited clinically.

Preclinical studies identified irinotecan as an active agent for treatment of several pediatric solid tumors [51,52], and that antitumor activity was optimal when irinotecan was administered over a protracted period. Currently, for pediatric indications, clinical administration of irinotecan is by short infusion daily for 5 days at 50 mg/m²/day (Children's Oncology Group), or for 5-days on two consecutive weeks at 20 mg/m²/day (St. Jude schedule). Alternatively, irinotecan is administered orally for 5 consecutive days at 90 mg/m², the higher dose reflecting the poor oral bioavailability of irinotecan both in mice and patients [53,54]. In contrast, PLX038 is administered by infusion over 60 minutes every 21 days, hence would be advantageous in terms of patient convenience and cost.

Following a single dose of PLX038A, 13 models (43%) were in PR (7) or CR (6) at week 3 following a single dose of PLX038A, and only 4 models (13%) had progressed (>25% increase in tumor volume), with other tumor models representing stable disease (SD; <25% progression, <50% regression). Thus, 87% of models would have been eligible for further treatment if representing a patient in a clinical context. A comparison of the activity of PLX038A and cycle 1 of irinotecan was available for 11 models. For PLX038A treatment, 7 (63%) had not progressed by day 21, hence would meet criteria for a second cycle of treatment. Analysis of the day-21 status of tumors in the cohort treated with irinotecan (2.5 mg/kg daily × 5), prior to starting a second cycle of irinotecan therapy, shows that 6/11 (54%) models had progressed (>25% increase in tumor volume over day-1 of treatment), whereas 5 models (45%) had PR/CR. Thus, using 'clinical' criteria, in the cohort of 11 models with data from both treatments, mice bearing 63% of models would qualify for at least one further treatment with PLX038A, whereas following one cycle of irinotecan only 45% would meet criteria for treatment with cycle 2.

Future development of PLX038 may well be dependent on demonstration of tolerability and activity in adult patients. Results presented here indicate that PLX038A in mice is highly active, and equal to or slightly superior to a single cycle of irinotecan. While it is accepted that mouse models can overpredict for activity in a clinical setting, irinotecan and PLX038A have the same mechanism of action, hence it would be anticipated that PLX038 would have activity against many pediatric cancers shown to be responsive to irinotecan. Future development in a pediatric setting would probably involve combining PLX038 with vincristine, as an effective combination, as well as with radiation therapy. Further preclinical studies testing such combinations may be valuable in advancing this agent to pediatric clinical trials.

Fig. 1.

Responses of 31 individual xenograft models in mice treated with a single administration of PLX038A. Tumor diameters were measured weekly until tumor reached endpoint criteria (4-fold volume at day of treatment) or day 140 when experiments were terminated.

Fig.2.

A, 'Waterfall' plot showing the maximal tumor volume regression (100% is a volume below level of detection $\sim 40 \text{ mm}^3$) in mice treated with a single administration of PLX038A; **B**, "Swimmer" plot showing the EFS for 31 xenograft models in treated xenografts. Tumors marked with an asterisk are those where there was no detectable tumor at termination of the experiment at day 140. **C**, The relationship between the maximal tumor volume reduction and EFS for 31 xenograft models in mice treated with PLX038A ($R^2 = 0.2293$). Arrows mark overlapping coordinates for SK-NEP-1 and RBD-2 [day 38] and Rh36, EW-8, TC-71, KT5 and KT11 [day 140]).

Fig. 3.

A, The relationship between EFS determined after irinotecan (2.5 mg/kg daily $\times$ 5; EFS(IRN)) and EFS following a single administration of PLX038A (EFS(PLX038A)). KT11 xenografts are identified as an outlier sensitive to PLX038A. Data for irinotecan are median EFS for groups of 10 treated mice; **B,** The same data without KT11 ($R^2 = 0.6844$).

Fig. 4. Differentially mutated genes between resistant and sensitive tumors. Solid black cell indicates a non-synonymous mutation. The three genes shown in the heatmap have the most significant p values ($p=0.18$) from Fisher’s exact test without reaching statistical significance.

Table 1.

Characteristics of pediatric xenograft models used.

Histotype	Subtype	Gender	Age (Yr)	Tumor Site	Status ¹
<u>Ewing Sarcoma</u>					
ES-1	Type 1 t(11;22)	F	45	Thigh	Dx ²
