Participation of peribiliary glands in biliary tract pathophysiology

Saya Igarashi, Yasunori Sato, Xiang Shan Ren, Kenichi Harada, Motoko Sasaki, Yasuni Nakanuma

Abstract

AIM: To investigate the roles of peribiliary glands around the bile ducts in the pathophysiology of the biliary tract.

METHODS: The expression of fetal pancreatic markers, pancreatic duodenal homeobox factor 1 (PDX1) and hairy and enhancer of split 1 (HES1) and endodermal stem/progenitor (S/P) cell markers [CD44s, chemokine receptor type 4 (CXCR4), SOX9 and epithelial cell adhesion molecule (EpCAM)] were examined immunohistochemically in 32 normal adult livers (autopsy livers) and 22 hepatolithiatic livers (surgically resected livers). The latter was characterized by the proliferation of the peribiliary glands. Immunohistochemistry was performed using formalin-fixed, paraffin-embedded tissue sections after deparaffinization. Although PDX1 and HES1 were more frequently expressed in both the nucleus and cytoplasm of epithelial cells, only nuclear staining was evaluated. SOX9 was expressed in the nucleus, while CD44s, CXCR4 and EpCAM were expressed in the cell membranes. The frequency and extent of the expression of these molecules in the lining epithelia and peribiliary glands were evaluated semi-quantitatively based on the percentage of positive cells: 0, 1+ (focal), 2+ (moderate) and 3+ (extensive).

RESULTS: In normal livers, PDX1 was infrequently expressed in the lining epithelia, but was frequently expressed in the peribiliary glands. In contrast, HES1 was frequently expressed in the lining epithelia, but its expression in the peribiliary glands was focal, suggesting that the peribiliary glands retain the potential of differentiation toward the pancreas and the lining epithelia exhibit properties to inhibit such differentiation. This unique combination was also seen in hepatolithiatic livers. The expression of endodermal S/P cell markers varied in the peribiliary glands in normal livers: SOX9 and EpCAM were frequently expressed, CD44s infrequently, and CXCR4 almost not at all. The expression of these markers, particularly CD44s and CXCR4, increased in the peribiliary glands and lining epithelia in hepatolithiatic livers. This increased expression of endodermal S/P cell markers may be related to the increased production of intestinal and gastric mucin and also to the biliary neoplasia associated with the gastric and intestinal phenotypes reported in hepatolithiasis.

CONCLUSION: The unique expression pattern of PDX1 and HES1 and increased expression of endodermal S/P cell markers in the peribiliary glands may be involved in biliary pathophysiology.

Core tip: Immunohistochemical analysis showed that pancreatic duodenal homeobox factor 1 was more frequently expressed in the peribiliary glands than epithelia lining the bile duct and was accompanied by the reciprocal expression pattern of hairy and enhancer of
Thirty-two histologically normal livers were obtained from our recent autopsy series with minimal autolytic changes and at least one tissue section was obtained from the hepatic hilus containing hilar bile duct(s) with peribiliary glands in each case. In addition, 22 hepatolithiasic livers were obtained from our surgical cases and the age and sex of these cases were similar to those of normal livers. All stone-containing bile ducts exhibited the marked proliferation of peribiliary glands and failed to show neoplastic biliary epithelial lesions[14,15] and at least two tissue sections were obtained from these stone-containing bile ducts in each case.

**Tissue preparation:** All tissue samples were fixed in 10% neutral buffered formalin and embedded in paraffin. More than 20 consecutive 4-μm-thick sections were cut from each paraffin block and one section was stained with hematoxylin and eosin (HE) for histological observations. The remaining sections were used for immunohistochemistry.

**Immunohistochemistry and its evaluation**

Immunostaining was performed using formalin-fixed, paraffin-embedded tissue sections of normal and hepatolithiasic livers. The antibodies and their sources, optimal dilution and antigen retrieval are shown in Table 1. After deparaffinization and the blocking of endogenous peroxidase, the sections were incubated first in a protein block solution (DakoCytomation), then overnight at 4 °C with the primary antibodies against PDX1 and HES1 and the markers for endodermal S/P cells (CD44s, CXCR4, SOX9 and EpCAM) in the lining epithelia and peribiliary glands immunohistochemically, using 32 normal livers and 22 hepatolithiasic livers, and then tried to evaluate the roles and significance of these markers in the biliary tract pathophysiologies in hepatolithiasis.
As positive controls, islet cells in normal pancreatic tissue (one case) for PDX1, fibroblasts in cirrhotic liver tissue (one case) for HES1, neural cells in a normal human brain (one case) for CXCR4, fibroblasts in cirrhotic liver tissue (one case) for CD44s, normal human embryonic tissue (one case) for SOX9, and bile ducts in a normal liver (one case) for EpCAM were used as shown in Table 1. Negative controls were carried out with non-immunized serum substituted for the primary antibodies, resulting in no signal detection.

Although PDX1 and HES1 were expressed in both the nucleus and cytoplasm of epithelial cells, only nuclear staining was evaluated. Sox9 was expressed in the nucleus, while CD44s, CXCR4 and EpCAM were expressed in the cell membranes. The immunoreactivity of epithelial cells in the lining epithelia and peribiliary glands was semi-quantitatively graded based on the percentage of positive cells, as follows: 0, no expression of each marker in the lining epithelia or peribiliary glands; 1+ (focal), the expression of each marker in less than one third of the lining epithelia and peribiliary glands, respectively; 3+ (extensive), the expression of each marker in more than two thirds of the lining epithelia and peribiliary glands, respectively; and 2+ (moderate), the expression of each marker in the lining epithelia and peribiliary glands between 1+ and 3+, respectively. The staining intensity was rather stronger in the cases of extensive expression and was rather weaker in the cases of focal expression.

**Statistical analysis**

Intergroup comparisons were made using Mann-Whitney's U test. The results were considered significant if the P value < 0.05.

**RESULTS**

**Expression of the fetal pancreatic markers (PDX1 and HES1)**

In normal livers, PDX1 was infrequently and focally expressed in the lining epithelia but was extensively expressed in the peribiliary glands, with 28 of 32 cases showing moderate to extensive expression (Figures 1A and 2A). In contrast, HES1 was extensively expressed in the lining epithelia, with 28 of 32 cases showing moderate to extensive expression (Figures 1B and 2B), while its expression was infrequent and focal in the peribiliary glands. The patterns for the expression of PDX1 and HES1 in the peribiliary glands and lining epithelia in hepatolithiatic livers were similar to those in normal livers.

**Expression of the endoderm S/P cell markers (SOX9, EpCAM, CD44s and CXCR4)**

In normal livers, SOX9 was frequently expressed in the lining epithelia and also in the peribiliary glands, with 17 and 18 cases showing moderate to extensive expression, respectively (Figure 3A). EpCAM was frequently expressed in the lining epithelia and peribiliary glands (Figure 3B), with the level of moderate to extensive expression. In hepatolithiatic livers, the degree of SOX9 expression was relatively low in the lining epithelia and relatively high in the peribiliary glands in comparison
with normal livers, whereas the frequency and degree of EpCAM expression in both the lining epithelia and peribiliary glands were similar to those in normal livers (Figure 4A and B).

CD44s was moderately to extensively expressed in the lining epithelia and peribiliary glands in 7 and 8 out of 32 normal livers, respectively (Figure 3C), and its expression in the lining epithelia and peribiliary glands was increased in the frequency and degree in the hepatolithiatic livers, with this increase being significant in the lining epithelia (P < 0.01) (Figure 4C). CXCR4 was expressed in the lining epithelia and peribiliary glands of two and one normal livers, respectively. Its expression in the lining epithelia and peribiliary glands was increased in the frequency and degree in the hepatolithiatic livers (Figure 3D), with this increase being significant in the lining epithelia (P < 0.01) (Figure 4D).

The number of peribiliary glands in hepatolithiatic livers was markedly higher than that in normal livers. Therefore, the actual number of glandular cells expressing each marker of these fetal pancreatic markers and endodermal S/P cell markers in the peribiliary glands could be regarded as more in hepatolithiatic livers than expected by the above-mentioned semi-quantitative approach.

**DISCUSSION**

The results of this study can be summarized as follows: (1) In normal livers, PDX1 was extensively expressed in the peribiliary glands and was infrequently expressed in the lining epithelia of the bile ducts, and while the opposite was true for HES1, this unique expression pattern was retained in hepatolithiatic livers; (2) Endodermal S/P cell markers were variably expressed in the peribiliary glands and EpCAM and SOX9 were frequently detected in the peribiliary glands of normal livers, whereas CXCR4 was rarely detected; and (3) In hepatolithiatic livers, the expression of the S/P markers, particularly CD44s and CXCR4, in the lining epithelia and peribiliary glands was increased. Taken together, the reciprocal expression of PDX1 and HES1 in the lining epithelia and peribiliary glands may be important for physiological maintenance of the biliary tract. The expression of endodermal S/P cell markers was variable in the peribiliary glands and tended to be higher in hepatolithiatic livers than in normal livers, implying the pathogenetic roles of S/P cells in the biliary pathophysiological changes of hepatolithiasis.

HES1 is known to inhibit or repress the differentiation of pancreas, whereas PDX1 is involved in its promotion. Our recent study supported their roles in the
biliary tract differentiation and maturation in humans\textsuperscript{[1,4]}. The present study showed that PDX1 was infrequently and focally expressed in the lining epithelia of normal livers, but was extensively expressed in the peribiliary glands. In contrast, HES1 was extensively expressed in the lining epithelia, although infrequently and usually focally expressed in the peribiliary glands. Taken together, it seems possible that the peribiliary glands expressing PDX1 in adults retain potential properties for the promotion of pancreatic development as seen in the biliary epithelia of the fetal bile duct, while the lining epithelia of the bile duct expressing HES1 keep properties for the inhibition of pancreatic development.

Our previous studies showed that the pancreatic exocrine acini were occasionally present in the peribiliary glands of adults and expressed enzymes such as amylase, lipase and chymotrypsin\textsuperscript{[17,18]}. Carpino \textit{et al}\textsuperscript{[12]} also reported that pancreatic genes such as CFTR were weakly expressed in the peribiliary glands\textsuperscript{[11,13]}. Thus, it seems possible that the peribiliary glands may have the

Figure 3 Expression of SOX9, epithelial cell adhesion molecule, CD44s and chemokine receptor type 4. A: SOX9 was expressed in the nuclei of the lining epithelia of hilar bile ducts in normal livers and of the peribiliary glands in hepatolithiatic livers (HL) (Immunostaining of SOX9, $\times$ 200); B: Many of the lining epithelial cells in the hilar bile ducts of normal livers were positive for epithelial cell adhesion molecule (EpCAM) and many of the acini in the peribiliary glands of hepatolithiatic livers were positive for EpCAM (Immunostaining of EpCAM, $\times$ 200); C: CD44s was focally expressed in the lining epithelia and peribiliary glands of hepatolithiatic livers (Immunostaining of CD44s, $\times$ 200); D: Chemokine receptor type 4 (CXCR4) was focally expressed in the lining epithelia and peribiliary glands of hepatolithiatic livers (Immunostaining of CXCR4, $\times$ 200).
potential to become pancreatic cells and the biliary tract can be regarded as an incomplete pancreas\cite{11-13}. Gerber et al\cite{19} proposed one hypothesis in which glandular cells within the peribiliary glands could migrate via their conduits and renew or replace the lining epithelia of the bile ducts. Sutton et al\cite{20} also showed that peribiliary glands renewed the biliary lining epithelia as a repair process. Taken together, glandular cells in the peribiliary glands may lose PDX1 expression but gain HES1 expression during their migration toward the lining layer. Interestingly, this unique expression pattern of PDX1 and HES1 in the lining epithelia and peribiliary glands was generally retained in hepatolithiatic livers, suggesting that the above-mentioned renewal process may be maintained in hepatolithiasis.

Recent studies have shown multipotent, endoderm S/P cells to be present in human peribiliary glands at all ages\cite{11-13}. In the studies using cell cultures and tissue explants, isolated cells of the peribiliary glands expanded \textit{in vitro} and these cells readily and efficiently showed cell lineages differentiating into liver, the biliary tree or pancreatic cells\cite{11-13}. It was found in this study that the markers of endodermal S/P cells such as EpCAM, CD44s, CXCR4 and SOX9\cite{11,12,13,14,15,16} were variably expressed in the peribiliary glands and also in the lining epithelium of hilar bile ducts, supporting that peribiliary glands are a niche for endodermal S/P cells\cite{11-13}. The different expression patterns of endoderm S/P cell markers may reflect heterogeneous S/P cell components within the peribiliary glands. Mucin hypersecretion is a frequent finding in cases of hepatolithiasis\cite{14,15,16}. Mucin secreted from the bile ducts is central to calcium bilirubinate stones. According to our previous studies, gel-forming mucins such as MUC2 and MUC5AC were shown to be important for the development of calcium bilirubinate stones and these mucins were detected in the glands showing the intestinal and gastric metaplasia in the bile ducts and peribiliary glands with hepatolithiasis. The increased expression of

![Figure 4 Distribution of SOX9, epithelial cell adhesion molecule, CD44s and chemokine receptor type 4 expression in normal and hepatolithiatic livers.](image_url)
Interestingly, the peribiliary glands were shown to be dense at the hepatic hilar regions, the cystic duct of gallbladder, and the periamplillary region, where cholangiocarcinomas (CCs) are likely to occur. Furthermore, CCs and precursor lesions, such as biliary intraepithelial neoplasm and intraductal papillary neoplasm of bile duct (IPNB), are known to develop in the stone-containing bile ducts in hepatolithiasis. This study showed that the expression of these S/P cell markers tended to be higher in the peribiliary glands and also lining epithelia of hepatolithiatic livers than in those of normal livers. CD44s-positive cells were also increased in the lining epithelia and peribiliary glands in hepatolithiatis, while CD44s was not typically expressed in the normal biliary tract. It was reported that CD44s was expressed in CCs, CXCR4 is a chemokine receptor, its interaction with its ligand was reportedly involved in cholangiocarcinogenesis and the frequent expression of CXCR4 in the lining epithelia and peribiliary glands was shown in this study. Taken together, this study suggested that CD44s and CXCR4 may also be related to the proliferative activities, therefore, it also seems likely that PDX1 expression in the peribiliary glands of hepatolithis may be related to their proliferation and neoplastic processes.

The increased expression of pancreatic and endodermal S/P cell markers in the lining epithelium and peribiliary glands may be also related to the unique features of the neoplastic processes of the biliary tract. Our recent study showed that PDX1, HES1 and PDX1/PDX2 were frequently expressed in the peribiliary glands of hepatolithiatis. Therefore, it is possible that the lining epithelia and peribiliary glands expressing pancreatic and endodermal S/P cell markers may be related to the similarities of hilar cholangiocarcinoma to PDAC and may also be involved in the intestinal or gastric metaplasia of hepatolithiatis. In conclusion, the peribiliary glands frequently and extensively expressed PDX1 but focally expressed HES1 and PDX1 and this unique expression pattern may be involved in the biliary tract maintenance. The expression of endodermal S/P cell markers in the peribiliary glands and also lining epithelium may be involved in the intestinal and gastric metaplasia occurring in these glands in hepatolithiasis. The lining epithelia and peribiliary glands expressing pancreatic and endodermal S/P cell markers in hepatolithiatis may be also involved in cholangiocarcinogenesis with pancreatic and gastrointestinal phenotypes. Further studies are needed to clarify the exact roles of the peribiliary glands expressing endodermal S/P cell markers in the pathophysiology of biliary diseases in hepatolithiatis.

**COMMENTS**

**Background**

Pancreatic duodenal homeobox factor 1 (PDX1), a transcription factor crucial for the development of the pancreas and a marker of pancreatic progenitor cells, was shown to be expressed in the fetal biliary tract. In contrast, hairy and enhancer of split 1 (HES1), which is also a fetal transcription factor that represses pancreatic exocrine and endocrine differentiation, is also important for the development and differentiation of the biliary tract.

**Research frontiers**

PDX1 was infrequently and focally expressed in the lining epithelia of normal livers, but was extensively expressed in the peribiliary glands. In contrast, HES1 was extensively expressed in the lining epithelia, although infrequently and usually focally expressed in the peribiliary glands. Taken together, it seems possible that the peribiliary glands expressing PDX1 in adults retain potential properties for the promotion of pancreatic development as seen in the biliary epithelia of the fetal bile duct, while the lining epithelia of the bile duct expressing HES1 keep properties for the inhibition of pancreatic development.

**Innovations and breakthroughs**

In this study, the authors examined the expression of fetal pancreatic markers (PDX1 and HES1) and endodermal stem/progenitor (S/P) cell markers in the lining epithelia and peribiliary glands immunohistochemically, using 32 normal livers and 22 hepatolithiatic livers, and then tried to evaluate the roles and significance of these markers in the biliary tract pathophysiology in hepatolithiatis.

**Applications**

The study’s unique combination was also seen in hepatolithiatic livers. The expression of these markers, particularly CD44s and chemokine receptor type 4, increased in the peribiliary glands and lining epithelia in hepatolithiatis. This increased expression of endodermal S/P cell markers may be related to the increased production of intestinal and gastric mucin and also to the biliary neoplasia associated with the gastric and intestinal phenotypes reported in hepatolithiatis.

**Peer review**

The authors have investigated the pathophysiology of peribiliary glands (currently known to be stem cell niches of pancreas and the biliary tree) in hepatolithiatis by performing immunohistochemistry using a set of fetal pancreatic markers and endoderm S/P cell markers. The present work clearly demonstrated the roles of peribiliary glands as biliary epithelial renewal and metaplasia and supported the previous findings as stem cell niches. It also provides interesting insights into the roles of peribiliary glands in inflammation-associated pancreatic duct cancer and cholangiocarcinoma.
