Abstract

Traffic and power generation are the main sources of urban air pollution. The idea that outdoor air pollution can cause exacerbations of pre-existing asthma is supported by an evidence base that has been accumulating for several decades, with several studies suggesting a contribution to new-onset asthma as well. In this Series paper, we discuss the effects of particulate matter (PM), gaseous pollutants (ozone, nitrogen dioxide, and sulphur dioxide), and mixed traffic-related air pollution. We focus on clinical studies, both epidemiological and experimental, published in the previous 5 years. From a mechanistic perspective, air pollutants probably cause oxidative injury to the airways, leading to inflammation, remodelling, and increased risk of sensitisation. Although several pollutants have been linked to new-onset asthma, the strength of the evidence is variable. We also discuss clinical implications, policy issues, and research gaps relevant to air pollution and asthma.

Introduction

Outdoor air pollution contributed more than 3% of the annual disability-adjusted life years lost in the 2010 Global Burden of Disease comparative risk assessment, a notable increase since the previous estimate was made in 2000. Previous assessments of global disease burden attributed to air pollution were restricted to urban areas or by coarse spatial resolution of concentration estimates. In a study of ten European cities, 14% of the cases of incident asthma in children and 15% of all exacerbations of childhood asthma were attributed to exposure to pollutants related to road traffic. Urbanisation is an important contributor to asthma and this contribution might be partly attributed to increased outdoor air pollution (figure 1). Because many urban centres in the developing world are undergoing rapid population growth accompanied by increased outdoor air pollution, the
global burden of asthma is likely to increase. In this context, it is notable that the populations of China, India, and Southeast Asia are equal to the rest of the world combined.

In view of the burden of asthma attributed to outdoor air pollution, a better understanding of why asthmatic individuals are susceptible to this exposure should enable the design of effective preventive strategies. The idea that air pollution can cause exacerbations of pre-existing asthma is supported by an evidence base that has been accumulating for several decades, but evidence has emerged that suggests air pollution might cause new-onset asthma as well. Not all studies support a causal link between air pollution and asthma, and a recent meta-analysis of cross-sectional studies that compared communities with different levels of pollution showed no effect of long-term exposure to pollution on asthma prevalence. Although outdoor air pollution almost always occurs as a mixture, air quality is regulated by most jurisdictions in terms of its individual components. Such regulation has meant that experimental studies of humans and animals have been focused on individual pollutants. Because epidemiological studies inherently involve exposure to mixtures of pollutants, substantial efforts are usually made to try to identify the individual effects of pollutants, which often obscures the health effect of the mixture as a whole.

With increasing attention to traffic-related air pollution (TRAP) as the exposure variable of interest, a shift has occurred away from a focus on individual components of the pollution mixture. In this Series paper, we will attempt to discuss the effects of several gaseous pollutants (ozone, nitrogen dioxide, and sulphur dioxide), the independent effects of various forms of PM, and then focus on the effects of TRAP as a mixture. We concentrate on studies published in the past 5 years that report results relevant to both exacerbation and onset of asthma.

We focus primarily, although not exclusively, on epidemiological and experimental clinical studies. Controlled exposure studies in human beings are restricted by small sample size and an inability to study the potentially most susceptible subgroups (eg, children and adults with severe asthma) and the effects of chronic exposure. Epidemiological studies are restricted by imprecise methods of both exposure and asthma outcome assessment and often inadequate data about potentially confounding variables.

Although the potential effect of indoor air pollution on asthma is an important concern, especially in developing countries where much domestic cooking is done with solid fuels, it is outside the scope of this review.

**Mechanisms**

Why are individuals with asthma so affected by exposure to air pollution? At high concentrations, such as those noted in megacities in India and China, air pollutants might have direct irritant and inflammatory effects on airway neuroreceptors and epithelium, but such levels of exposure rarely occur in North America or Europe. At the lower concentrations that are more typical in high-income countries, other mechanisms are probably in operation. Specific pollutants can induce airway inflammation (eg, ozone, nitrogen dioxide, and PM <2.5 μm in diameter [PM2.5]) and airway hyper-responsiveness (ozone and nitrogen dioxide), two characteristic features of asthma. In
addition, oxidative stress (a feature of severe asthma) has been associated with pollutant exposures (ozone, nitrogen dioxide, and PM2.5). Therefore, exposure to these pollutants is unsurprisingly associated with exacerbations and possibly even the onset of asthma. The mechanisms by which pollutants induce these effects are not completely clear.

A framework for how air pollution might contribute to the development and exacerbation of asthma proposed by the UK’s Committee on the Medical Effects of Air Pollutants identified four main mechanisms: oxidative stress and damage, airway remodelling, inflammatory pathways and immunological responses, and enhancement of respiratory sensitisation to aeroallergens (figure 2). Variation in the genes that regulate these mechanisms could confer increased susceptibility to development of new-onset asthma or exacerbations of existing disease with exposure to air pollution.

Because the pollutants of interest, including TRAP, can cause oxidative stress, the ability of antioxidant defences to handle the increased load of reactive oxygen species generated in the lungs after exposure is an important determinant of risk for subsequent adverse effects. Specific polymorphisms in antioxidant enzyme genes, such as glutathione S-transferase genes, GSTM1 and GSTP1, can modify risk of asthmatic responses to pollutants and these variants (GSTM1 null and GSTP1 Ile105Val) might also interact with a tumour necrosis factor (TNF) promoter variant (G-308A) that affects expression of TNF and hence the early inflammatory response. Additionally, neonatal rats are more prone to oxidative stress from PM exposure at least in part due to relative deficiency of nuclear factor-like 2 (Nrf2). Proinflammatory effects of oxidative stress are mediated by the redox-sensitive MAP kinase and nuclear factor-κB cascades that are responsible for the expression of cytokines, chemokines, and adhesion molecules, and reduced antioxidant capacity in the airways can result in altered expression after pollutant exposure.

Other pathways through which oxidising pollutants might affect severity of asthma involve control of immune responses. TRAP, specifically ambient polycyclic aromatic hydrocarbons and diesel-exhaust particles, affect regulatory T cell (Treg) function through an epigenetic mechanism. Hypermethylation of CpG islands in Foxp3 associated with chronic exposure to polycyclic aromatic hydrocarbons or diesel-exhaust particles leads to suppression of Treg function and increased asthma severity as assessed by symptoms and lung function. Hypermethylation of interferon γ in effector T cells, contributing to a shift towards a Th2 response, has also been associated with exposure to air pollution. Studies in animals and in vitro suggest that exposure to PM results in allergic inflammation with Th2 and Th17 phenotypic differentiation, with a specific role for environmentally persistent free radicals and polycyclic aromatic hydrocarbon fractions of PM in this differentiation. In addition, exposure to diesel-exhaust particles is associated with increased serum interleukin 17 and increased symptoms in children with allergic asthma; a parallel study that used a murine model of allergic airway inflammation showed that combined exposure to diesel-exhaust particles and antigen from a house dust mite induced a mixed Th2/Th17 response.
A potential enhancing effect of pollutant exposure on responses to inhaled allergen has been studied in both animals and man, with evidence for such an effect on lung function and inflammatory responses to ozone, nitrogen dioxide, sulphur dioxide, and diesel-exhaust particles.\textsuperscript{45–48} Several mechanisms through which air pollutants could enhance sensitisation to aeroallergens have been proposed and include increased deposition of allergen in the airways due to carriage by particles, increased epithelial permeability due to oxidative injury, increased antigenicity of proteins from chemical modification, and a direct adjuvant effect (including for diesel-exhaust particles in human beings).\textsuperscript{49}

In summary, air pollutants might cause oxidative injury to the airways that leads to inflammation and remodelling, which in a genetically predisposed individual could result in clinical asthma. One predisposing factor might be atopy, and air pollutants could increase the risk of sensitisation and the responses to inhaled allergen in individuals with asthma.

### Particulate matter

Ambient PM is a ubiquitous atmospheric aerosol with both anthropogenic and natural sources that has been associated with various health effects.\textsuperscript{50} PM is categorised on the basis of its aerodynamic diameter, with implications for its typical site of deposition when inhaled (figure 3). Coarse PM, with an aerodynamic diameter of 2·5–10 μm, deposits mainly in the head and large conducting airways. Fine PM or PM2·5 deposits throughout the respiratory tract, particularly in small airways and alveoli. Ultrafine PM (<0·1 μm) deposits in the alveoli. PM10 includes the coarse, fine, and ultrafine fractions (figure 4). The composition and size distribution of PM varies according to the source, whether it is natural or anthropogenic, and whether it is derived from combustion or not.\textsuperscript{50} Transition metals, polycyclic aromatic hydrocarbons, and environmentally persistent free radicals are constituents of PM of special interest because of their potential to cause oxidative stress and many of the phenotypic changes associated with asthma. Additionally, PM frequently contains various immunogenic substances, such as fungal spores and pollen, which have been independently associated with exacerbation of asthma symptoms.\textsuperscript{51,52}

Experimental exposure to PM results in oxidative stress, airway hyper-responsiveness, and airway remodelling, either alone or in combination with allergic sensitisation.\textsuperscript{53}

Short-term exposure to ambient PM2·5 and PM of diameter 2·5–10 μm in prospective cohorts of asthmatic children and adults has been associated with asthma symptoms, especially in children with allergic sensitisation.\textsuperscript{54,55} Long-term exposure to PM is associated with poorly controlled asthma and decrements in lung function in children and adults.\textsuperscript{30,56} Several studies in children and adults have shown associations between short-term and long-term exposure to PM2·5 or PM10 and increased health-care use; these associations are generally partially attenuated but persistent after adjustment for co-pollutants.\textsuperscript{57–63}

Some evidence suggests PM is a cause of incident asthma (aside from the literature on TRAP). Independent associations between exposure to PM10 in utero and during infancy with asthma diagnosed by a doctor were identified in a nested case-control study within a large birth cohort.\textsuperscript{18} Although several studies have identified associations between asthma
prevalence and exposure to outdoor PM, this finding has not always been consistent. Furthermore, PM is frequently strongly correlated with ozone, nitrogen oxides, and sulphur oxides, serving to confound these associations. In summary, substantial evidence supports the idea that ambient levels of PM exacerbate existing asthma, particularly by contributing to oxidative stress and allergic inflammation, and some evidence exists in support of PM as a cause of new cases of asthma.

Gases

In view of the central role of oxidative stress in asthma morbidity associated with air pollutants, oxidising gases continue to be an area of substantial research. Ground-level ozone is formed by photochemical reactions between sunlight and pollutant precursors, such as nitrogen oxides and volatile organic compounds, especially in warm conditions and peaks in summer temperatures. Nitrogen oxides, including nitrogen dioxide, are formed primarily by the reaction of ozone with nitric oxide emitted during fossil fuel combustion; as a result, steep concentration gradients of nitrogen oxides exist near sites of nitrogen oxide emission (eg, roadways) and relative depletion of ozone occurs in these sites. Indoor exposure to nitrogen dioxide derives from appliances that burn natural gas. The main sources of sulphur oxides in the developed world are primary emissions during energy production or industrial processes. These gaseous pollutants vary substantially in their environmental persistence and oxidising capacity; whereas ozone is a potent oxidising agent, nitrogen dioxide is a relatively weak oxidant and much debate surrounds whether it is a cause of asthma morbidity or just a marker of TRAP. Because sulphur dioxide is a reductant, it probably causes asthma symptoms through a different mechanism.

Responses to controlled exposure of short-term ozone and sulphur dioxide at relevant concentrations have been studied extensively. Ozone exposure results in airway inflammation, airway hyper-responsiveness, and decrements in lung function in healthy and asthmatic adults, whereas sulphur dioxide causes more prominent bronchoconstriction, especially in asthmatic individuals (table 1). Controlled exposure to nitrogen dioxide seems to have a mild airway inflammatory effect at high levels of exposure that are unlikely to be encountered in non-experimental settings, but induces little lung inflammation at common ambient concentrations. A 1992 meta-analysis identified an increase in airway hyper-responsiveness with relevant concentrations of nitrogen dioxide, but a 2009 review showed this effect to be small, inconsistent, and of unclear clinical significance. Consequently, focus has been placed on the adjuvant role nitrogen dioxide might have in combination with exposure to copollutants or allergens.

By contrast with the inconsistent experimental data on nitrogen dioxide, the body of observational data supporting its role in the exacerbation of asthma and asthma incidence continues to grow in breadth and consistency. Studies of asthmatic children and adults in the past 5 years have identified associations between nitrogen dioxide and symptoms of asthma, reduced response to bronchodilators, decrements in lung function, and exacerbation of asthma. Notable, several studies have identified an increase in asthma incidence or prevalence associated with exposure to nitrogen dioxide. Biological plausibility for nitrogen dioxide as a cause of asthma is supported by experimental data from...
animals and controlled exposures of healthy and asthmatic adults, showing enhanced pulmonary neutrophilic inflammation and the promotion of a Th2/Th17 phenotype, although not all studies of asthmatic patients showed such an effect of nitrogen dioxide. Despite weaknesses in toxicological data, consistent results from observational studies over a broad range of exposures and in diverse populations suggest that nitrogen dioxide is associated with significant morbidity in asthmatic individuals and might be a cause of incident asthma.

Although short-term exposure to ozone has been well documented as a cause of asthma exacerbation in adults and children, whether long-term exposure can lead to new-onset asthma is somewhat less clear. Studies of adult-onset asthma have identified an increased risk associated with ozone exposure, although this effect was restricted to male individuals. In children, ozone has been associated with incident allergic sensitisation, a known risk factor for subsequent asthma, and prevalence of wheeze and asthma as diagnosed by a doctor. Studies of asthma incidence in children have identified an association with ozone, although the risk might be confined to heavily exposed, physically active children. Taken together, the available evidence suggests that ozone might be a cause of new-onset asthma in some subgroups of children.

Although exposure to sulphur dioxide has been greatly reduced in the developed world through the use of scrubbing equipment in coal-fired power plants and energy sources other than coal combustion, it is a problem in developing countries. A study from China noted an association with sulphur dioxide and both asthma prevalence and current symptoms among children, especially in those with atopy.

**TRAP**

TRAP is a complex mixture of PM derived from combustion (including elemental or black carbon) and non-combustion sources (eg, road dust, tyre wear, and brake wear) and primary gaseous emissions including nitrogen oxides. These primary emissions lead to the generation of secondary pollutants such as ozone, nitrates, and organic aerosol. Intense experimental and epidemiological research has greatly advanced our understanding of the role of TRAP in asthma and disease mechanisms underlying this association, facilitated in part by advances in modelling that allow improved spatial resolution of exposure than can be provided by central site air quality monitors. Concentrations of many of the constituent pollutants in TRAP diminish quickly with distance from roadways. A 2010 review suggested that distances within 300–500 m of roadways were the most relevant for effects on human health. In large North American cities, 30–45% of people live within this distance of a major roadway, and the burden of near-roadway exposure seems to be even higher in many European cities.

Diesel-exhaust particles, in isolation, have inconsistent effects in animals and in vitro. However, exposure to such pollutants concomitant with or after sensitisation to a variety of allergens, results in oxidative stress, airway hyper-responsiveness, enhanced neutrophilic and eosinophilic airway inflammation, and a switch to Th2/Th17 phenotypes. Mice exposed prenatally to diesel-exhaust particles develop more substantial postnatal manifestations of allergic asthma after allergen sensitisation and upregulation of genes.
involved in oxidative stress responses and polycyclic aromatic hydrocarbon metabolism. Controlled human exposure of asthmatic individuals enhances non-specific airway hyper-responsiveness, but not airway inflammation. By contrast, healthy individuals develop airway inflammation without airway hyper-responsiveness.

Epidemiological studies of TRAP relying on various exposure metrics have identified increases in respiratory symptoms, changes in lung function, and healthcare use in children and adults. Notably, the phase 3 ISAAC study, representing over 500,000 children and adolescents across five continents, identified a dose-response association between symptoms of asthma (ever asthma, current wheeze, and severe asthma symptoms) and self-reported exposure to truck traffic. Effects of short-term ambient exposure to PM2.5, nitrogen oxides, and carbon monoxide were increased by exposure to higher than median modelled traffic exposure, showing the strength of considering both regional air pollution and long-term TRAP exposure in studies of health effects. A study of two communities in Southern California estimated that reductions in traffic-related nitrogen dioxide and ozone to background levels would reduce bronchitic episodes in asthmatics by 36–70%. The London Low Emission Zone provides an opportunity to study the impact of reduced TRAP on asthma morbidity. Collectively, these data suggest that TRAP exposure, especially in urban areas, has a tremendous effect on disease morbidity in individuals with asthma.

A growing body of evidence supports the notion that TRAP exposure is also responsible for cases of incident asthma. Several recent prospective studies of children with never-asthma at enrolment have identified an increased incidence associated with greater TRAP exposure. A future source of information on early exposures related to asthma incidence will be the ENRIECO project in Europe, a collaboration of multiple birth cohort studies. Adults with never-asthma at baseline have an increased risk of incident asthma associated with TRAP. In two studies, asthma prevalence in ten European cities at least partially attributable to near-road TRAP was 14% and total cases of incident asthma in Los Angeles County attributable to traffic proximity was 8%. In view of this growing body of evidence supporting TRAP’s role in exacerbation of underlying asthma and, probably, development of new cases of asthma, we suggest additional focus be placed on assessment of the effect of strategies aimed at reduction of these exposures.

**Risk modifiers**

Young children with asthma have long been regarded as a group who are very susceptible to adverse effects from air pollution because of their developing lungs, immature metabolic pathways, high ventilation rates per bodyweight, and increased time exercising outdoors. Even exposures in utero might affect postnatal risk of asthma and asthma exacerbations. Low birthweight, which might be associated with narrow airways during early childhood, is a risk factor for symptoms of asthma related to air pollution.

Asthma exacerbations are more prevalent and severe in young boys than in girls and this disparity has been attributed, at least in part, to relatively narrow airways in early life. No consistent difference in air pollution effects on asthma has been evident between boys and girls.
girls, although some studies have reported differential responses based on sex.\textsuperscript{54,104} In adults, active asthma is more prevalent among women than men,\textsuperscript{103} but again no consistent sex-based difference in risk has been noted for exacerbations related to air pollution. Elderly individuals with asthma are likely to be at increased risk for adverse effects related to air pollution, but scant literature is available to support this point.

Evidence to support differences in susceptibility to air pollution on the basis of ethnicity in asthma is also restricted, but the incidence of asthma was associated with exposure to air pollution in African–American and Latino children recruited from several US cities and Puerto Rico.\textsuperscript{12} Effects of ethnicity might be confounded with those effects associated with low socioeconomic status. Asthmatic children of such families seem to have greater exposure to outdoor air pollution and greater susceptibility to the effects of pollutants than do children from families of high socioeconomic status.\textsuperscript{105–107} The factors that might contribute to this susceptibility include neighbourhood characteristics (eg, increased levels of crime, less green space, or poor food access), stress,\textsuperscript{108} and diet.

Dietary factors can play a part in susceptibility to pollutant effects independent of socioeconomic status. The body of evidence on the protective effects of a diet high in fruits and vegetables and of antioxidant vitamin supplements is sufficient to support an important role for oxidative stress in the pathways by which outdoor air pollution adversely affects asthma.\textsuperscript{109–111} Obesity might also increase susceptibility to the adverse effects of air pollution.\textsuperscript{112–114}

Because secondhand tobacco smoke is a mixture that includes gases and respirable PM and is known to adversely affect asthma, it would be expected to be a modifier of the effects of air pollution. Some evidence is available to support this expectation.\textsuperscript{101,115} What is clear is that polymorphisms of genes (\textit{GSTM1}, \textit{GSTP1}, and \textit{TNF}) that have been associated with susceptibility to adverse asthma outcomes from exposure to air pollutants have also been associated with increased risks from exposure to secondhand smoke.\textsuperscript{116–118}

**Clinical implications**

One strategy to reduce exacerbations of asthma related to air pollution is for local governments to issue smog alerts on days when ozone or PM\textsubscript{2.5} levels are forecast to be high (table 2). Individuals with asthma and other pre-existing cardiopulmonary disorders are urged to stay indoors on such days. Clinicians should encourage patients with asthma (and advise parents of children with asthma), to avoid unnecessary outdoor activity, especially if it entails vigorous exercise that increases minute ventilation and thus the total inhaled dose, on days when air pollution levels are high. Avoidance of outdoor activity on poor air quality days can be added to a patient’s asthma management plan. For such an avoidance strategy to be effective, however, jurisdictions ought to publicise air quality monitoring data widely and on a daily basis. Although data on the effectiveness of smog alerts are scarce, some evidence suggests that people do avoid going outdoors when alerts are issued in Southern California (especially people with known susceptibility).\textsuperscript{88–90,119}

Patients with asthma should ideally live at least 300 m from major roadways, especially those with heavy truck traffic. TRAP can exacerbate asthma,\textsuperscript{10,120} but concentrations of
motor vehicle emissions such as ultrafine PM and black carbon particles decrease substantially by 300 m.\textsuperscript{121} In-vehicle exposure during commuting with open windows can also be very high.\textsuperscript{122}

Treatment of exacerbations of asthma related to air pollution need not differ from usual clinical practice. In addition to avoidance of exposure on high pollution days, exacerbations can be prevented by maintenance inhaled corticosteroid therapy as several studies suggest this approach decreases adverse responses to pollutant exposures.\textsuperscript{123,124} Patients with severe asthma might be the most likely to have respiratory symptoms with exposure to air pollutants, despite treatment with steroids.\textsuperscript{125} Because of the potential interactive effects of air pollutants with allergens or secondhand smoke, avoidance of these exposures is prudent, especially during high pollution days, which may be concurrent with exposure to seasonal aeroallergens.

**Policy issues**

Motor vehicle emissions and power plants are the main sources of both primary pollutants (eg, nitrogen oxides, fine PM, and ultrafine PM) and secondary pollutants (eg, ozone, nitrates, sulphates, and organic aerosol) in developed countries. Although improved pollution controls have reduced emissions of pollutants, growing evidence of adverse health effects at levels less than present US, Canadian, and European Union standards suggests that cleaner vehicles and energy production that do not rely on combustion of fossil fuels will be necessary to achieve good air quality. Climate change is projected to increase ozone concentrations in many locations because of increased sunshine and ambient temperature.\textsuperscript{126} Because mitigation of climate change and depletion of the world’s oil reserves also require reduced reliance on fossil fuels, policy initiatives to incentivise the development of alternatively powered vehicles and renewable electricity production might be advisable.\textsuperscript{127,128}

Efforts to reduce greenhouse gas emissions would have a major co-benefit in terms of lowering of primary and secondary emissions of air pollution. Thus, governments should coordinate their climate change mitigation and clean-air regulation efforts as California is trying to do.\textsuperscript{129} Governments could prioritise mitigation measures that increase human health benefits from clean air, for example by focusing on carbon sources with the most toxic PM emissions such as coal and diesel combustion.\textsuperscript{130} Elimination of coal burning, rather than regulations requiring electrostatic precipitators or scrubbers on power plant smokestacks, would maximise reduction of carbon dioxide and PM2.5 emissions. Increased production of power from non-fossil fuels is key to reduction of reliance on coal combustion.

Control of air pollution in developing countries is usually complicated by efforts to accelerate economic growth, the costs of both alternative energy production and control measures, and household air pollution from the inefficient burning of solid fuels (eg, wood, dung, crop waste, and coal). Cities in countries with rapid economic and population growth, such as China and India, have some of the worst air quality in the world.\textsuperscript{131} Both countries burn a lot of coal and the number of motor vehicles on their roads is increasing rapidly.
Therefore, China’s commitment of substantial resources into alternative power production is encouraging, as is India’s recognition of the need to reduce domestic cooking with biomass fuels. However, present efforts are insufficient to address both the climate change and public health imperatives of rapidly increasing fossil fuel combustion for power and transportation needs (figure 5). One concept that offers reduced reliance on coal and provision of power in the less developed rural areas of developing countries is decentralised or distributed generation, referring to electricity production at or near the point of use.133

Smart growth strategies are also necessary to reduce vehicle travel in the megacities of developing countries and in the developed world.134 Government investment in efficient public transportation systems and support of high-density, energy-efficient housing along transit system corridors will reap long-term economic and public health benefits. The paradox of urban intensification is a major concern. At the neighborhood level, improvements to public transportation will usually be insufficient to counteract the traffic congestion effect of increasing population density. This problem leaves policy makers with a poor choice: intensify and accept the local consequences or allow urban sprawl and accept the wider consequences. To address this paradox, some cities are implementing intensification accompanied by parking restrictions, closing roads to traffic, congestion pricing, and car-free zones.135

**Research gaps**

Although much research on air pollution and asthma has been done in the past 5 years, major gaps in our knowledge remain. Perhaps the most critical gap is in our understanding of the mechanisms by which exposure to air pollutants contributes to the onset of asthma, especially in non-atopic children and adults. Gene–environment interaction is an obvious focus of future research. The biological basis for the interactive effects of air pollution and psychological stress is another especially intriguing area in which our understanding is low.

In view of how important air pollution is as a trigger of exacerbations, improved mechanistic understanding of how these exacerbations occur is needed so that strategies to prevent them can be developed. Although exposure to PM2·5 and TRAP is associated with increased risk of asthma exacerbations, which components of the particulate mix are the most responsible is not known (eg, fine vs ultrafine particles). Nitrogen dioxide, a relatively mild oxidant at ambient concentrations, is repeatedly noted in epidemiological studies as the pollutant most associated with effects on asthma, but the reason is unclear. Is nitrogen dioxide merely a good marker of exposure to TRAP or is it involved in a biological pathway leading to asthma exacerbation? Polycyclic aromatic hydrocarbons are another class of pollutants about which more information is needed. Several recent papers have suggested that these compounds play a part in both allergy and asthma in children,39,101,136 and the epigenetic pathway in which they play a role makes these ubiquitous products of combustion a prime target for future research.

In addition to the specific chemical characteristics of air pollutants, another key question is whether short-term peak exposures (eg, 1 h) versus time-weighted averages over longer time periods (eg, 1–2 days) are associated with increased risk of adverse asthma outcomes. Some
evidence points to peak exposures being more important than long-term exposure, although more data are needed to address this question. Furthermore, what lag time exists between exposure to air pollutants and clinical effect? Many studies show a strong effect on the day after high-level pollutant exposure, rather than on the day of exposure. Finally, although exposure science has made great strides over the years, assessment of individual-level exposure is presently primarily based on either distance from air quality monitoring stations or estimates from models. Methods for personal monitoring might allow individuals to assess their own exposure.

One of the most challenging tasks for air pollution research has been how to address the fact that people are almost always exposed to a mixture of pollutants. Effective strategies to address this confounding are needed for both epidemiological and toxicological studies. Cumulative impacts of pollutant exposures in concert with other environmental stressors (eg, stress, poor diet, or tobacco smoke) is another challenging concept for which innovative strategies are needed. The relative contributions of pollutant exposures in indoor microenvironments—home, school, workplace, transit—is also understudied, but new technologies are in development that might allow assessment of exposure in these locations.

The adverse effects of exposure to air pollutants might vary over the life course such that future research should be directed toward differential effects at different stages of development. Even prenatal exposures to pollutants might affect risk of disease later in life, including asthma.

Climate change will lead to increases in ambient concentrations of pollutants, ozone (directly), and nitrogen dioxide and PM2·5 (secondary to increased energy production required for air conditioning). Increased exposures to aeroallergens are also projected because of lengthened growing seasons and increased production of pollen. Thus, improved understanding of pollutant exposure-allergy interactions will be needed to address the expected increased risk of asthma exacerbations from the confluence of these effects of climate change.

Conclusions

A substantial body of research on the effects of air pollution on asthma has been published in the past 5 years, adding to the body of knowledge that has accumulated over several decades. Presently, short-term exposures to ozone, nitrogen dioxide, sulphur dioxide, PM2·5, and TRAP is thought to increase the risk of exacerbations of asthma symptoms. Increasing amounts of evidence also suggest that long-term exposures to air pollution, especially TRAP and its surrogate, nitrogen dioxide, can contribute to new-onset asthma in both children and adults. Much more about the mechanisms that are involved with exacerbations induced by pollution and onset of asthma needs to be understood, but oxidative stress and immune dysregulation are probably both involved. Young children with asthma, especially those growing up in economically disadvantaged neighbourhoods, are at increased risk of adverse effects from exposures to air pollution. Unravelling which components of the traffic pollution mixture are responsible for asthma exacerbations and...
onset is a substantial challenge. Improved air quality to prevent exacerbations and new cases of asthma will require strong governmental efforts to move economies in both developed and developing countries away from combustion of fossil fuels for transportation and energy production; this approach is also needed to mitigate climate change.

Search strategy and selection criteria

We searched Pubmed from Jan 1, 2009, to Feb 28, 2014, with the search terms “Asthma” and any of the following specific terms: “Air Pollution”, “Particulate Matter”, “PM2·5”, “PM10”, “Ozone”, “O3”, “Sulfur Dioxide”, “Sulfur Oxides”, “SO2”, “SOx”, “Nitrogen Dioxide”, “Nitrogen Oxides”, “NO2”, “NOx”, “Traffic”, “Diesel”, “Elemental Carbon”, or “Black Carbon”. We searched the reference lists of recent reports and review articles produced with this search strategy to include relevant publications older than 5 years. Additionally, we included frequently referenced older publications with a high impact based on our knowledge of the subject area, particularly when more recent publications on the same subject were not available.

UK Daily Air Quality Index is based on concentrations of nitrogen dioxide, sulphur dioxide, ozone, PM2.5, and PM10. Similar air quality indices exist for many other countries, differing in the pollutants considered and recommendations offered. PM2.5=particulate matter with a diameter of less than 2.5 μm. PM10=particulate matter with a diameter of less than 10 μm.
