ABSTRACT

INTRODUCTION Frailty is becoming increasingly prevalent in the elderly population although a lack of consensus regarding a clinical definition hampers comparison of clinical studies. More elderly patients are being assessed for surgical intervention but the effect of frailty on surgical related outcomes is still not clear.

METHODS A systematic literature search for studies prospectively reporting frailty and postoperative outcomes in patients undergoing surgical intervention was performed with data collated from a total of 12 studies. Random effects meta-analysis modelling was undertaken to estimate the association between frailty and mortality rates (in-hospital and one-year), length of hospital stay and the need for step-down care for further rehabilitation/nursing home placement.

RESULTS Frailty was associated with a higher in-hospital mortality rate (pooled odds ratio [OR]: 2.77, 95% confidence interval [CI]: 1.62–4.73), a higher one-year mortality rate (pooled OR: 1.99, 95% CI: 1.49–2.66), a longer hospital stay (pooled mean difference: 1.05 days, 95% CI: 0.02–2.07 days) and a higher discharge rate to further rehabilitation/step-down care (pooled OR: 5.71, 95% CI: 3.41–9.55).

CONCLUSIONS The presence of frailty in patients undergoing surgical intervention is associated with poorer outcomes with regard to mortality and return to independence. Further in-depth studies are required to identify factors that can be optimised to reduce the burden of frailty in surgical patients.

KEYWORDS
Frailty – Elderly – Postoperative outcomes – Mortality rates – Sarcopenia

The aging population alongside technological advances in surgical and anaesthetic techniques present surgeons with increasing dilemmas as to whether to intervene on elderly patients with a number of surgical conditions in both the elective and emergency setting.1,2 It is well recognised that age is a predictor of poorer postoperative outcomes, which in turn predict poor long-term survival.3,4 Nevertheless, not all older patients have poor surgical outcomes. The concept of frailty is a recognised syndrome in the field of elderly medicine (although there is little consensus on its exact definition),5,6 and there is recognition of an overlap between frailty and other geriatric syndromes including sarcopenia.7,8 This lack of definition has resulted in a lack of consensus on the optimal method to determine frailty.9

Not all elderly patients have a frailty phenotype, which suggests that frailty is not an inevitable consequence of aging and as such, may be amenable to treatment. The presence of a frailty phenotype has potential significance in an elderly surgical population as perioperative frailty related interventions may improve outcomes. However, it is essential to first determine what effect frailty has on the outcomes of commonly performed surgical procedures. The aim of this study was to estimate the association between frailty and adverse patient events in surgical patients using meta-analysis.

Methods

An electronic search was undertaken using the PubMed and MEDLINE® databases from 1 January 1980 to 1 October 2012. The search employed the terms ‘frailty’ and ‘sarcopenia’ combined with the terms ‘surgery’, ‘postoperative’ and ‘hospital discharge’. Abstracts of the citations identified by the search were scrutinised by two of the authors (KO and RN) to determine eligibility for inclusion in the analysis. Studies were deemed eligible if they were purely prospective studies, included surgically related outcomes (specifically mortality rates, complication rates, length of stay [LOS] and need for postoperative placement in rehabilitation facilities) and reported on at least 50 patients.
There is no widely accepted definition of frailty. Scores relating to functional or cognitive dependence, weight, muscle mass and co-morbid illness have been developed but these have not been widely adopted or standardised. It is therefore not yet possible to capture a frail population using one discrete definition. As a consequence, studies were eligible if they defined frailty objectively and had a comparator ‘non-frail’ group. Patients undergoing all forms of surgery (elective and emergency) except surgery for fractured neck of femur were included. Fractured neck of femur patients were excluded as the widespread involvement of orthogeriatricians could bias the comparability of these patients. Further references were found through scrutinised review of the bibliographies of selected articles to identify any articles missed by the searches.

Outcomes of the meta-analysis were 1-year mortality and early mortality (ie in-hospital mortality). For studies where in-hospital mortality was not reported, 30-day mortality or mortality ‘following surgery’ were used. Other outcome measures assessed were LOS and requirement for step-down rehabilitation placement. Overall and organ specific complication rates, where reported, are also summarised in this review.

Statistical analysis
All analyses were performed using the random effects model for meta-analysis, employing the DerSimonian and Laird method. The meta-analyses of binary outcomes (in-hospital and one-year mortality, need for rehabilitation) used study specific log odds ratios (comparing frail with non-frail patients) as outcome data, and the resulting pooled estimates and confidence intervals were converted to odds ratios (ORs). Since the binary outcomes were all adverse events, a positive OR indicated that frailty is associated with worse patient outcomes. The LOS meta-analysis used study specific mean differences of LOS as outcome data, where a positive mean difference indicated that frailty is associated with longer hospital stays.

All analyses used numerical values (eg percentages, counts, means) reported by the studies. In some circumstances, further calculations were needed to ascertain the outcome data but no values were obtained by attempting to read them from graphs. Twelve studies were deemed suitable for meta-analysis. Six studies provided outcome data for two distinct groups of patient groups (‘frail’ and ‘non-frail’ groups). One study provided outcome data for four groups but identified one of these groups as patients with sarcopenia; this group was used for frail data. The other five studies provided data for multiple patient groups and did not define a threshold to indicate frailty.

With the exception of the study by Sündermann et al, data from the frailest group of patients provided our frail outcome data and the other groups were combined to provide our non-frail outcome data. However, as the most frail group (‘severely frail’) in the study by Sündermann et al contained only 19 patients (0%) and also because the next most frail group consisted of 95 clearly frail (‘moderately frail’) patients (45%), it was decided to combine the severely and moderately frail data to provide frail outcome data. This decision was made prior to performing the statistical analyses that follow.

In two studies, a single patient in the group of patients defined as being frail died. These single deaths are not included in the in-hospital mortality meta-analysis because the zero counts in the corresponding non-frail group would require artificial correction to include them in the random effects meta-analysis and the resulting normal approximation would be especially crude and could result in bias, especially for relatively small studies such as these.

The study by Makary et al provided mean lengths of hospital stay but did not report the associated standard deviations. This information is needed for the calculation of the within-study variance of the mean difference. As a result, the data for LOS from this study were not used. The 2011 study by Peng et al provided data on LOS stratified by sex. The pooled (across the two sexes) standard deviations for this study were therefore used to calculate the corresponding within-study variance.

The results from the meta-analyses are presented as pooled ORs (with 95% confidence intervals [CIs]) for in-hospital mortality, one-year mortality and the requirement for step-down rehabilitation. The pooled mean difference (with 95% CI) is presented for the LOS. I² statistics are also presented to describe the extent of the between-study heterogeneity. Other postoperative complications were investigated qualitatively.

Results
A total of 385 potentially relevant articles were identified (Fig 1), of which 12 met the inclusion requirements for our systematic review, corresponding to a total of 7,960 patients (Table 1). Of the 7,500 patients for whom sex was reported, 5,392 were men (73.9%). Of the twelve studies, one assessed patients undergoing elective non-cardiac surgery, four assessed patients undergoing cardiac surgery, six assessed patients undergoing gastrointestinal/hepatopancreaticobiliary surgery and one assessed patients undergoing open abdominal aortic aneurysm surgery (Table 1). The objective measures of frailty used in each study are documented in Table 1.

In-hospital/one-year mortality
In-hospital 30-day mortality was reported in 6 studies (Table 2). The pooled OR for the association between frailty and in-hospital mortality was 2.77 (95% CI: 1.62–4.75, I²=16%). One-year mortality rates were reported in five studies. The pooled OR for the association between frailty and one-year mortality was 1.99 (95% CI: 1.40–2.66, I²=0%).

Length of stay
Data for LOS were available in four studies. The pooled mean difference between the LOS for frail and non-frail patients was 1.05 days (95% CI: 0.02–2.07 days, I²=21%).
Need for step-down rehabilitation
Six studies reported on the need for step-down rehabilitation. The pooled OR was 5.71 (95% CI: 3.41–9.55, $I^2=61\%$).

Postoperative complications
Postoperative complication rates were presented in seven studies (Table 3). Owing to the limited amount of information available, meta-analyses were not performed using these data but some observations are briefly summarised here. In four studies, there were notable differences between frail and non-frail groups with the frail groups showing greater complication rates. The reverse was seen in two studies and one study was equivocal.

Discussion
The syndrome of frailty is common with an estimated prevalence in excess of 10% in community dwelling adults aged 65 years and over, and higher levels seen with increasing age and in women. The issue of frailty has been brought to prominence in the UK with the National Confidential Enquiry into Patient Outcome and Death publication. One of the principal recommendations was that co-morbidity, disability and frailty need to be recognised as markers of risk in the elderly. Our meta-analysis shows that following surgical intervention, frailty is associated with higher in-hospital and one-year mortality, longer length of hospital stay and increased requirement for step-down care to rehabilitation facilities or nursing homes.

Frailty itself can be theoretically defined as a clinically recognisable syndrome of increased vulnerability as well as age associated decline in reserve and function. In clinical practice, there is a lack of a standard definition and this is reflected by the varying definitions of frailty used by the studies identified in this review. Fried et al defined frailty as meeting three of five phenotypic criteria indicating compromised physicality (eg slowed walking speed). Peng et al diagnosed frailty as loss of psoas muscle mass on diagnostic imaging. A 2015 publication focusing on determining a definition did not reach consensus.

Although the precise definition of frailty is yet to be determined, the concept that it leads to poor outcome following surgery still stands. The studies included in this review were heterogeneous in their study populations and definition of frailty but the effect of frailty (particularly on in-hospital and one-year mortality) was consistent.

The biological basis for the effect of frailty is yet to be fully understood, and may include changes at a cellular level (eg oxidative damage) and systemic changes associated with medical co-morbidities. Cumulative co-morbidity may lead to poor outcome as patients may develop complications directly related to their medical condition or they may simply have reduced physiological reserve.

Separating frailty from specific co-morbidities or disability is difficult, especially as many of the frailty scores incorporate co-morbid illness. In this review, there were too few

*The Edmonton frail scale incorporates the domains of cognition, general health status, functional independence, social support, medication use, nutrition, mood, continence and functional performance, and is scored out of 17.
The results of this systematic review suggest that issues associated with frailty should be addressed to improve patient outcomes. An easily identifiable definition that is applicable in clinical practice needs to be formulated and research to determine this must be undertaken. It is also essential to ascertain which specific aspects of the frailty phenotype bring about such poor outcomes. This may differ depending on the specific surgical population and pathology operated on, and it is the key to establishing how best to improve frailty in surgical patients. Irreversible frailty should be taken into account when deciding whether to proceed to surgical intervention and this may improve the process of informed consent. Conversely, the identification of potentially reversible components of frailty not only provides an opportunity for surgical optimisation but also has wider benefits, particularly in terms of social and health economic planning.
