Wheat, rice, maize, and soybean provide two-thirds of human caloric intake. Assessing the impact of global temperature increase on production of these crops is therefore critical to maintaining global food supply, but different studies have yielded different results. Here, we investigated the impacts of temperature on yields of the four crops by compiling extensive published results from four analytical methods: global grid-based and local point-based models, statistical regressions, and field-warming experiments. Results from the different methods consistently showed negative temperature impacts on crop yield at the global scale, generally underpinned by similar impacts at country and site scales. Without CO2 fertilization, effective adaptation, and genetic improvement, each degree-Celsius increase in global mean temperature would, on average, reduce global yields of wheat by 6.0%, rice by 3.2%, maize by 7.4%, and soybean by 3.1%. Results are highly heterogeneous across crops and geographical areas, with some positive impact estimates. Multimethod analyses improved the confidence in assessments of future climate impacts on global major crops, with independent methods consistently estimated negative temperature impacts on yields of four major crops at the global scale, generally underpinned by similar impacts at country and site scales. Multimethod analyses improved the confidence in assessments of future climate impacts on global major crops, with important implications for developing crop- and region-specific adaptation strategies to ensure future food supply of an increasing world population.

Several methods have been developed to assess the impact of temperature increase on crop yields (6). Process-based crop models characterize crop growth and development in daily time steps and can be used to simulate the temperature response of yield either in areas around the globe defined by grids or at selected field sites or points (1, 7). A third method, statistical modeling, uses observed regional yields and historical weather records to fit regression functions to predict crop responses (8, 9). A fourth method is to artificially warm crops under near-natural field conditions to directly measure the impact of increased

Significance

Agricultural production is vulnerable to climate change. Understanding climate change, especially the temperature impacts, is critical if policymakers, agriculturalists, and crop breeders are to ensure global food security. Our study, by compiling extensive published results from four analytical methods, shows that independent methods consistently estimated negative temperature impacts on yields of four major crops at the global scale, generally underpinned by similar impacts at country and site scales. Multimethod analyses improved the confidence in assessments of future climate impacts on global major crops, with important implications for developing crop- and region-specific adaptation strategies to ensure future food supply of an increasing world population.

Climate change impact | global food security | major food crops | temperature increase | yield

Crop yields are sensitive to climate change, including changes in temperature and precipitation, and to rising atmospheric CO2 concentration (1, 2). Among the changes, temperature increase has the most likely negative impact on crop yields (3, 4), and regional temperature changes can be projected from climate models with more certainty than precipitation. Meteorological records show that mean annual temperatures over areas where wheat, rice, maize, and soybean are grown have increased by ~1 °C during the last century (Fig. 1A) and are expected to continue to increase over the next century (Fig. 1B) —more so if greenhouse gas emissions continue to increase. It is thus necessary to quantify the impact of temperature increase on global crop yields, including any spatial variations, to first assess the risk to world food security, and then to develop targeted adaptive strategies to feed a burgeoning world population (5).
temperatures (4). Here, we combine these four methods, which use disparate data sources, time spans, and upscaling approaches (10), to assess the impact of increasing temperatures on yields of wheat, maize, rice, and soybean. Grid- and point-based simulations from recent international model intercomparison exercises (2, 7, 11, 12) and published results of 13 statistical regression estimations from recent international model intercomparison exercises (SI Appendix, Figs. S1 and S3), but estimates varied between countries. The impact estimates are consistently negative for four major maize producers, together responsible for two-thirds of global maize production—namely, the United States (−10.3 ± 5.4% per degree Celsius), China (−8.0 ± 6.1% per degree Celsius), Brazil (−5.5 ± 4.5% per degree Celsius), and India (−5.2 ± 4.5% per degree Celsius). The estimated impact on maize crops in France, however, is smaller (−2.6 ± 6.9% per degree Celsius), including a small positive estimate (3.8 ± 5.2% per degree Celsius) from statistical modeling (13).

For wheat, the average estimate from all four methods is a 6.0 ± 2.9% loss in global yield with each degree-Celsius increase in temperature (Fig. 2A). Results from the four methods agree more closely on the impact on wheat (−7.8 to −4.1% per degree Celsius) than on maize yields (Fig. 2A). The results from different methods are also generally consistent for the top five wheat-producing countries (Fig. 2A) that harvest >50% of the world’s wheat. Spatially, however, the impacts are highly heterogeneous. Estimated wheat yield losses for the United States (−5.5 ± 4.4% per degree Celsius) and France (−6.0 ± 4.2% per degree Celsius) are similar to the global average, while those for India (−9.1 ± 5.4% per degree Celsius) and Russia (−7.8 ± 6.3% per degree Celsius) are more vulnerable to temperature increase. The large yield reductions for Russia are mainly due to the contribution of a markedly higher negative result from the statistical method (−14.7 ± 3.8% per degree Celsius; Fig. 3C), which did not account for in-season variations in temperature impact (10). By contrast, for China, the largest wheat producer in the world, the multimethod estimate indicates that only 2.6 ± 3.1% of yield would be lost for each degree-Celsius increase in global mean temperature.

Rice is a main source of calories in developing countries. The analysis from the multimethod ensemble indicates that a global increase in temperature of 1 °C will reduce global rice yield by an average of 3.2 ± 3.7%, much less than for maize and wheat (Fig. 2A). Grid- and point-based simulations and field-warming experiments indicate a negative impact of temperature of approximately −6.0% per degree Celsius, but some statistical regressions suggest almost no impact. Similar disparities in estimates between the statistical regressions and other methods are found for several major rice-producing countries (Fig. 3B).
including China, which produces ~30% of the world’s rice (14). Similar regression methods produce quite different estimates for Indonesia, Bangladesh, and Vietnam, which, when averaged across all methods, lead to small estimated impacts on rice production for each country. For India, however, estimates from all methods predict large temperature impacts, with a multimethod average of $-6.6 \pm 3.8\%$ per degree Celsius.

Soybean is the fourth most important commodity crop (14). Results of just three studies using only two methods are available for global-scale estimates of the impacts of temperature on soybean yield. The global average reduction in soybean yield is 3.1% per degree-Celsius rise (Fig. 24), but the estimates are not statistically significant due to large uncertainties in each method (the 95% CIs go through zero). Similar effects are estimated with both methods for the United States, Brazil, Argentina, and Paraguay (Fig. 3D), which produce 84% of the global soybean harvest (14). The largest expected reduction is $-6.8 \pm 7.1\%$ per degree Celsius for the United States, the largest soybean producer. The overall results for China, the fourth largest producer, however, do not indicate statistically significant effects of temperature on soybean yield.

We compared different methods for a total of 10 sites and found that method estimates are similar for most site-crop combinations.
(Fig. 4). Estimates from grid- and point-based simulations are more similar to each other than to field-warming observations (Fig. 4 and SI Appendix, Fig. S4). This is not unexpected, as the two types of simulation have some methodological similarities, such as model structure, assumptions, and parameters. The grid- and point-based models both tend to project greater yield loss with increasing temperature at warmer locations and less yield loss at cooler locations, a distinction not identified in the field experiments (SI Appendix, Fig. S4).

Some of the impact differences between simulations and field experiments could be due to the fact that field experiments were only carried out over a few years and might not represent the entire variability of climate at this location, while the simulations represent 30 y. Simulation parameters are also based on the properties of cultivars that differ from those grown in field experiments. For example, the field experiment in Wageningen (The Netherlands) indicated a large negative impact of temperature rise on wheat yield (~11.6% per degree Celsius), but used a spring wheat that is not representative of the region (15). Positive impacts (11.2 ± 1.2% per degree Celsius) were observed in wheat (A), rice (B), and maize (C) or from two methods for soybean (D). Grid-Sim, Point-Sim, and Point-Obs are grid-based simulations, point-based simulations, and field-warming experiments, respectively. Regres_L-N are site-, county- or city-scale regression analyses for specific crops shown by labels L-N next to the mean of the plotted dataset. Error bars are 95% CIs. Error bars for the Jinzhou (China) results for regression L are not available.

Fig. 4. Site-based multimethod ensemble of crop yield changes with 1 °C of global temperature increase. Site estimates from more than three methods are shown for wheat (A), rice (B), and maize (C) or from two methods for soybean (D). Grid-Sim, Point-Sim, and Point-Obs are grid-based simulations, point-based simulations, and field-warming experiments, respectively. Regres_L-N are site-, county- or city-scale regression analyses for specific crops shown by labels L-N next to the mean of the plotted dataset. Error bars are 95% CIs. Error bars for the Jinzhou (China) results for regression L and N were not available.

**Materials and Methods**

**Temperature Data.** Historical observed gridded monthly temperature data are from the Climate Research Unit (0.5° × 0.5° grid, CRU TS 3.23; https://crudata.uea.ac.uk/cru/data/temperature). Future predicted temperature data are from the Coupled Model Intercomparison Project Phase 5 (CMIP5) Earth System Models (ESMs) outputs (1.0° × 1.0° grids; cmip-pcmdi.llnl.gov/cmip5) used in the Intergovernmental Panel on Climate Change (IPCC) Assessment Report 5 (28). According to data availability, the outputs from 15, 20, 11, and 22 ESMs were included in this study for RCP2.6, RCP4.5, RCP6.0, and RCP8.5 scenarios, respectively. However, the calculated temperature changes are very similar to those calculated by using all of the ESMs (IPCC 5). The annual mean temperature over the global growing area of an individual crop was calculated by weighting each grid cell average (0.5° × 0.5° grids) according to the crop growing area within the grid cell (29).

**Global Gridded Crop Model Simulations.** The Agricultural Model Intercomparison and Improvement Project (AgMIP) (30) and Inter-Sectoral Impact Model Intercomparison Project (ISIMIP) (31) initiated a fast-track global crop assessment for the main global crops in 2012, including wheat, rice, maize, and soybean. Seven global gridded crop models were used to simulate crop yield in 0.5° × 0.5° grid cells over the globe, forced with climate reconstruction for a global warming scenario near +4 °C (RCP8.5) are likely to be conservative due to the nonlinear impact of rising temperatures in the real world (4, 18). A nonlinear response to temperature has also been suggested in simulations (1, 7, 10).

To prepare for adaptation to climate change, it is necessary to isolate the effects of individual factor for possible impacts on yield, as changes in different factors usually require different adaptation strategies. While elevated atmospheric CO₂ concentration can stimulate growth when nutrients are not limited, it will also increase canopy temperature from more closed stomata (19). Also, changes in precipitation can have an effect on crops, but projections on precipitation change are often uncertain. The focus of our study is on temperature change, one of the most direct negative impacts from climate change on crops, and does not include other possible climate change effects from elevated atmospheric CO₂ concentration or changes in rainfall, and possible deliberate adaptation taken by farmers. Farmers have increased yields through adapting new technologies during the last half-century, but yield has been also lost through increases in temperatures already (9). Yield increase has slowed down or even stagnated during the last years in some parts of the world (20, 21), and further increases in temperature will continue to suppress yields, despite farmers’ adaptation efforts.

The direct negative temperature impact on yield could be added up to be affected via indirect temperature impacts. For instance, increasing temperature will increase atmospheric water demand, which could lead to additional water stress from increased water pressure deficits, subsequently reducing soil moisture and decreasing yield (22, 23). However, an accelerated phenology from increased temperatures leads to a shorter growing period and less days of crop water use within a cropping season. Such indirect temperature effects are taken into account in each of the methods, but are not explicitly quantified. Other indirect temperature impacts include more frequent heat waves and possible temperature impacts on weeds, pests, and diseases (18, 24–26). All increases in management intensity and yield potential could also unreasonably increase yield sensitivity to weather (27).

By combining four different methods, our comprehensive assessment of the impacts of increasing temperatures on major global crops shows substantial risks for agricultural production, already stagnating in some parts of the world (20, 21). However, differences in temperature responses of crops around the world suggest that some mitigation could be possible to substantially affect the magnitude (or even direction) of climate change impacts on agriculture. These impacts will also vary substantially for crops and regions, and may interact with changes in precipitation and atmospheric CO₂, so a reinvigoration of national research and extension programs is urgently needed to offset future impacts of climate change, including temperature increase on agriculture by using crop- and region-specific adaptation strategies.
1980–2099 based on HadGEM2-ES (32) derived from CMIP5. The simulations were carried out under a scenario of constant CO2 concentration (380 ppm in 2000) and full irrigation, to exclude the possibility of covariance with CO2 and precipitation. More detailed information about the simulations can be found in refs. 1 and 33. Temperature impact values were calculated from yield changes between 2029 and 2058 (+2 °C of global mean temperature) and 1981–2010 (baseline), which were then halved to give +1 °C of global temperature impact. For global or country results, all of the grids were averaged by weighting the corresponding growing area of each crop (29).

Point-Based Ensemble Simulations. The AgMIP (30) also conducted crop yield simulations at 30, 4, and 4 representative sites around the world (SI Appendix, Fig. 51) by using 30 wheat, 13 rice, and 19 maize models, respectively. For wheat, a scenario of +2 °C was created by adjusting each day's temperature by +2 °C relative to the baseline (1981–2010), with other factors being constant. For rice and maize, the +3 °C scenarios were used. Model details about simulations for each crop can be found in refs. 7, 11, and 12. The temperature impact was calculated as the yield change during the warming period relative to the yield during the baseline period normalized to +1 °C impact, assuming the impact showed a linear temperature response. To obtain values for impacts at the country scale, each country was deemed to be similar to one or more representative sites located in the same or nearby country. As local temperature changes are different from the country mean, the local point-based estimates were scaled up by multiplying each country's temperature factor produced by HagGEM2-ES (28), as in ref. 7. The weighted average temperature impacts over all of the countries were used to estimate the global scale impact, weighted by country-level production (14). It should be noted that the results from only four sites were used to represent all of the rice- and maize-producing countries, which might not encompass all of the uncertainties from diverse production systems and is also one limitation in our analysis.

No point-based model-ensemble simulations for soybean were conducted in AgMIP.

Field-Warming Experiments. We started with all published peer-reviewed studies that applied artificial warming treatments on field crops. To avoid the risks from only selecting crops that received 24-h warming treatments for >2 mo. Results from laboratory incubators or controlled environments with constant day–night temperature treatment (e.g., 37/29 °C vs. 29/21 °C) were excluded. The studies with temperature change (ΔT) unequal to +1 °C were adjusted to +1 °C impact by dividing the impact value by ΔT, which assumed a linear relationship between impacts and ΔT. The studies that produced temperature impacts of >50% per °C were deemed as outliers and excluded. A total of 46 published studies (available from the corresponding author upon request) and 48 sites (SI Appendix, Fig. 51) were therefore included in the following analysis. Most of the sites (41 of 48) had a warming magnitude of 1.5–3.0 °C, similar to the grid- and point-based simulations. The upscaling methods from site to country to global scale are the same as for the point-based model simulations.

Statistical Regressions. Statistical models used regression equations to link historical year-to-year variations in yield to variations in selected climate variables. Different detrending methods were applied in the model to remove the influence of adaptation measures, such as crop management. In the statistical regression study used here, the global-level results of regressions A and B (Fig. 2A) used detrending methods with the inclusion of a quadratic time trend and first differences, respectively, and resulted in more similar temperature impacts than grid- or point-based simulations. A similar result was found for the country-level regressions A and C (the country-level results are in Fig. 3), which used detrending methods with inclusion of a quadratic time trend and first-differences method, respectively. The results from statistical models were from 13 published studies (available from the corresponding author upon request). The interannual fluctuation in temperature over the globe is ~2 °C (8), similar to the warming magnitude used in other methods. To ensure comparability of results, reported values under local temperature changes were normalized to global surface temperature changes by multiplying the corresponding temperature factor produced by HagGEM2-ES (28).

Multimethod Ensemble. The above four methods constituted the method ensemble that we used to estimate multimethod means and uncertainties. In this study, values from the method ensembles were synthesized at site, country, and global scales. At the country scale, the temperature impacts from regression methods were only reported for the five countries producing each crop; thus, the results mainly focus on the relevant top five countries. The uncertainty for the method ensemble was calculated by using a formula: var(Υ) = var(E(Y(method)) + EVar(Y(method)), where the term var(E(Y(method)) is a measure of the variability between methods, and E[Var(Y(method))] is a measure of the average variability within methods, assuming that this is random sample of approaches from a population of approaches. Confidence interval (CI) at 95% was calculated for the multimethod mean as: 95% CI = mean of methods ± 1.96 × var(Υ).

Comparisons Between Methods. A recent study by Liu et al. (2016) (10) compared the temperature impacts on wheat yield estimated by three different methods. We extended the analyses by including a large number of datasets from site-based observations (field-warming experiments) and comparing estimated impacts on yields of wheat, rice, maize, and soybean—the four most important staple crops for humans. At the country scale, different methods were compared across countries. For the regression method, the results were only reported for the five major countries producing each crop, and thus the comparisons only focused on the relevant five countries. At the site scale, grid-based simulations were compared with site-based simulations and field-warming experiments. Grids containing sites of point-based simulations or warming experiments were selected. The comparisons included absolute yield under different temperature scenarios and relative temperature impacts. The baseline and temperature period for each grid was determined when the rolling 30-y annual mean temperature was equal to the baseline and increased temperatures used for point-based simulations and experiments. The temperature impact was calculated as the yield changes relative to the baseline and then adjusted to a +1 °C global temperature impact.

Prediction of Yield Changes by the End of Century. The yield change by the end of century was calculated as the products of the ensemble estimated yield response and projections of global temperature rise from CMIP5. As the yield response (Fig. 2A) and predicted temperature change (Fig. 18) both have uncertainties, a bootstrap resampling approach was used to obtain the predicted yield change and its uncertainty. At each instance of bootstrap resampling, one pair of values for yield response and temperature change was sampled, respectively, from their original data to calculate the predicted yield change; this procedure assumes the chosen value is a random sample from a population of values. Repeating the above process 5,000 times gave 5,000 values of predicted yield change, which constitute a new distribution of the predicted yield change. The 2.5th–97.5th percentile was deemed as the boundaries of uncertainty for the predicted yield change.
